Introduction

8 Jha and colleagues introduce the case for increased funding of five health
9 interventions to control chronic disease in low and middle income
10 countries: a 33% tax on tobacco; acute management of heart attacks with
11 low cost drugs; prevention of heart attacks and stroke through salt
12 reduction by a mix of voluntary manufacturing changes, behaviour
13 change using mass media and other awareness raising campaigns;
14 prevention of hepatitis B through immunisation; and secondary
15 prevention of heart attacks and stroke through a combination of 3–

1 4 drugs in a ‘generic risk’ pill¹. The benefit/cost ratios range, in order,
2 from 40:1 to 4:1.

3 The determination of priorities begins with a focus on the current
4 and expected future burden of disease, as measured by deaths, avoidable
5 mortality, and cost of illness. The ‘very approximate’ (Jha et al 2012^{BIB-3-1}
6 ³⁻¹) discounted benefit-cost ratios are based on comparing a monetised
7 value of a disability adjusted life year (DALY) with intervention cost.
8 Evidence on interventions draws largely from the second Disease Control
9 Priorities Project (DCP 2) (Jamison et al 2006^{BIB-3-1}), Copenhagen
10 Consensus 2008 paper on disease control (Jamison et al 2008^{BIB-3-1}) and
11 selected other literature with a reflection that the investments proposed
12 reflect views of other similar exercises. The five benefit-cost ratios are
13 subject to sensitivity analyses of single and combined changes in the
14 following assumptions; changing the discount rate from 3% to 5%,
15 increasing all costs by 300%, and increasing the value of a DALY from
16 \$1000 to \$5000.

17 The benefit-cost ratios are supplemented, to indicate a move to an
18 ‘idealised’ version, by ‘accounting’ for the value of financial protection
19 and non-financial costs (e.g. transaction, organisational and
20 administrative effort to implement the intervention). The ‘accounting’ is a

¹ E.g. use of aspirin, a statin and an antihypertensive drug (Jamison et al
2008^{BIB-3-1})

1 categorisation that relies on: a literature review of various aspects of
2 health system capacity and; a review of the (limited) evidence on costs
3 and effects of the Chronic Care Model and its very limited adapted
4 application to low resource settings. This, at least partly, influences the
5 qualitative ratings based on the ‘speculative’ judgement of financial
6 protection and ‘non-financial’ costs by the authors. All interventions are
7 argued to offer high financial protection with only the impact of
8 ‘capacity’ differentiating the proposed interventions; tobacco taxation is
9 considered to have low capacity requirements, a salt reduction
10 programme to have medium capacity requirements and the others to have
11 high capacity requirements.

12 The paper ends by calling for an increased role for donor
13 assistance in controlling chronic diseases despite a concern that this ‘may
14 not be politically feasible in the short or even medium term’. This role is
15 also charged to ‘conduct research which makes the marginal costs of
16 (interventions) affordable’ and includes both more research and
17 development of relevant health technologies as well as implementation
18 research to close the gap between knowledge and action.

19 There is a real challenge in drawing together a justified list of
20 priorities for funding in an area which is recognised as being both short
21 of evidence in terms of geographical coverage and range of interventions
22 evaluated ([Suhkre et al 2012^{BIB-3-1}](#)) and hampered by poor quality

1 studies (Mulligan et al 2006^{BIB-3_1}). The paper by Jha and colleagues is
2 therefore a valiant effort to put forward the case for investment in an area
3 of human life that has a worrying future health and economic impact.

4 This perspective paper considers whether the best interventions
5 for investing in the in the improvement of chronic disease are presented
6 in the challenge paper. It considers: the influence analysis of burden of
7 illness analysis might have had and should have; the construction and
8 testing of BENEFIT-COST ratios for the five interventions selected; and
9 the approach taken to reflecting uncertainty. The paper ends by
10 suggesting alternative interventions for the expert panel to consider.

A

11 **Questioning the influence of burden of illness**

12 The paper appears to reflect the premise that the decision problem should
13 be framed in terms of the burden of disease and, having accounted for the
14 size of burden, focus on the set of cost-effective interventions to reduce
15 the burden. Evidence presented points to mental health conditions having
16 the highest economic burden using the cost-of-illness method and the
17 second largest using the value of lost output method. However, no
18 interventions are proposed for addressing this burden. By implication the
19 authors may have applied a burden of disease approach inconsistently,
20 adopted a very restricted definition of burden of disease or considered
21 evidence on benefit-cost ratios for all mental health interventions to be
22 less than 4:1. These possibilities are considered below.

1 It is not clear how estimates of burden in the challenge paper have
2 been used in practice to narrow down towards the selected interventions.
3 For example, a burden of illness approach based on mortality rates in
4 [Table 1](#) would suggest that ischemic and hypertensive heart disease
5 should be the focus of all interventions. However, this is not the case as
6 the selected of interventions aim at alleviating heart disease, stroke and
7 cancer². Use of avoidable mortality might explain the discrepancy but
8 these data are not provided by disease and therefore the potential
9 influence of this approach is unclear. Two further possibilities are that
10 either the burden of disease approach has been applied inconsistently or it
11 not been the lens through which cost-effective interventions are selected.
12 However, if burden of disease is not the original frame it doesn't explain
13 why so much information on burden of disease presented without
14 reference to the impact of health interventions.

15

Insert table 3.1.1 here

16 Perhaps interventions to improve mental health are absent because
17 the impact on mortality is comparatively low. There is a notable absence
18 of cause of death attributed directly to mental health in [Table 1](#) and a
19 statement that “we focus chiefly here on changes in mortality simply
20 because it is far less likely to be misclassified than are the more

² Given an assumption that mortality gains from tobacco tax are split
equally between cancer and heart disease.

1 subjective measures of disability”. Valuation of health benefits in the
2 benefit-cost ratio therefore only appear to account for disability averted
3 when tied to cases of premature mortality. This suggests first that the
4 burden and impact of chronic disease is massively underestimated as
5 highly morbid low mortality chronic diseases will be missing from any
6 estimate of burden presented here. Indeed co-authors of the
7 challenge paper conclude elsewhere ([Bloom et al, 2011^{BIB-3_1}](#))
8 that cardiovascular disease and mental health conditions are the
9 dominant contributors to the global economic burden of non-
10 communicable diseases. Secondly, it implies a further restriction
11 imposed by the particular burden of disease approach adopted in the
12 challenge paper – that cost-effective interventions aimed at alleviating
13 conditions with lower mortality rates are highly unlikely to be
14 recommended regardless of their cost-effectiveness. For a proposal
15 focussed on best buys for reducing chronic disease, this seems somewhat
16 limited and means that the investment proposals presented are unlikely to
17 reflect the best possible investment possibilities for reducing chronic
18 disease.

19 The possibility that the benefit-cost ratios for all mental health
20 interventions are less than 4:1 is a moot point and the authors provide no
21 evidence to support or refute this position. However, evidence from
22 DCP2 ([Jamison et al 2006^{BIB-3_1}](#), p40), on which the challenge paper

1 itself draws, supports the case that interventions to reduce mental health
2 are valid contenders to the proposals offered in the challenge paper.

3 Evidence from DCP2 ([Jamison et al 2006^{BIB-3_1}](#), p40) indicates
4 cost-effectiveness ratios for mental health interventions in the area of
5 alcohol abuse are around \$600–800/DALY averted and that treatment for
6 depression by drugs with episodic or maintenance psychosocial
7 treatment) is roughly \$900–3000/DALY averted. The detailed
8 DCP2 chapter by [Hymen et al \(2006\)^{BIB-3_1}](#) suggested that treatment of
9 depression with episodic treatment using older tricyclic antidepressants
10 ranged (by World Bank region) between \$478–1,288/DALY averted.
11 More recent evidence suggests that several mental health interventions
12 could be provided for under \$1000/DALY averted in both sub-Saharan
13 Africa and South East Asia. These include a bundle aimed at alcohol
14 reduction (including tax increase, reduced access and tax enforcement),
15 episodic treatment of depression with newer antidepressants (selective
16 serotonin reuptake inhibitors) and treatment of epilepsy with older anti-
17 epileptics at 80% coverage ([Chisholm et al 2012^{BIB-3_1}](#)).

18 Evidence presented in [Jamison et al \(2006^{BIB-3_1}](#), p41) for the
19 five selected interventions suggests that interventions to improve mental
20 health compare well. For example, legislation with public education to
21 reduce salt content was shown to have a cost/DALY averted of around
22 \$2,000 and secondary treatment of AMI and stroke with a polypill to be

1 around \$700/DALY averted. It is likely therefore, that benefit-cost ratios
2 of 4:1 or greater for mental health interventions may exist and be on a par
3 with several of the interventions proposed. This is particularly likely
4 because the challenge paper converts disability adjusted life years
5 (DALYs) lost to a monetary value to estimate benefit-cost-ratios without
6 accounting for other non-money values.

7 While the absence of interventions for improving mental health
8 may be of concern, it is only an example and many other cost-effective
9 interventions could be missing. Of particular concern, given the lack of
10 clarity in the use of burden of disease estimates in selecting interventions
11 in this case, is that the proposals could be systematically biased against
12 recommending the most cost-effective interventions. Why are some
13 potentially cost-effective treatments of chronic diseases missing? Some
14 justification of interventions narrowly missing inclusion (e.g. in terms of
15 benefit-cost ratios or the other criteria) would have helped illuminate the
16 authors approach more clearly.

17 Whilst there is unease with the mechanics of using the burden of
18 illness approach adopted here, of much greater concern is why a burden
19 is illness approach is used to structure the decision problem. Counting the
20 size of the epidemiologic or economic problem may indicate problems
21 for which there are no solutions and could lead to distorted priorities as
22 more cost-beneficial interventions might never even be considered

1 (Williams 1999^{BIB-3-1}, Wiseman and Mooney 1998^{BIB-3-1}). Beginning
2 with benefit-cost ratios first is more appropriate as it is a solution
3 focussed approach. It allows a fuller range of potential interventions to be
4 considered regardless of the focus of disease. It is possible that the most
5 cost beneficial intervention would also address the disease of highest
6 burden, but not necessarily.

7 It is important to recognise that the challenge paper authors were
8 limited to recommending a maximum of five interventions. In this case it
9 is not unreasonable to consider burden of disease estimates in order to
10 benefit from more of the set budget of \$75bn. However, to provide the
11 best buy would require considering benefit-cost ratios *before* considering
12 burden of disease. As the methods of combining information on disease
13 burden and benefit-cost ratios are not clear, it is possible this was done,
14 but this would be important to see.

A

15 **Construction and sensitivity of the benefit-cost ratios;**

16 ‘Indicative’ benefit-cost ratios are presented in Table 7 of the challenge
17 paper with details of calculation presented in the text and sensitivity
18 analysis in the Appendix. Reflecting past research on immunisation for
19 hepatitis B (Brenzel et al 2006; Sanderson 2005^{BIB-3-1}) I opted to
20 replicate and reconsider one of the options, using the approach presented
21 in the paper. Column 2 of Table 1 shows the replication. This indicates a
22 7:1 ratio which, through the rounding in Table 7 and further recalculation

1 to reflect the rounding was increased by the authors to 10:1 (Verguet,
2 personal communication). The replication therefore satisfactorily reflects
3 the assumptions of the challenge paper.

4 The assumptions specific to the hepatitis B vaccination option
5 were:

6 <listing>

- NL 7 a. cost per vaccinated child was \$3.6, reflecting a study of
8 India's national hepatitis B vaccination programme,
- NL 9 b. all benefits would occur 40 years after immunisation;
- NL 10 c. of the 600,000 annual deaths from hepatitis B reported
11 by WHO, a quarter were considered avoidable by
12 increasing global vaccination rates from 75% to 100%.

13 </listing>

14 While vaccine effectiveness was referred to as 75 and 95%, the increase
15 from 75–100% coverage appears to implicitly assume 100%
16 effectiveness, as all 150,000 deaths were considered avertable. All other
17 assumptions (e.g. value of a DALY averted, discount rate, DALYs lost
18 per death) were constant across investment options.

19 In reviewing the benefit-cost calculations three questions arose;
20 Why were particular data and assumptions adopted?; How valuable were
21 the sensitivity analyses in exploring these issues?; and, What is the
22 potential impact of adopting different assumptions?

1 Little justification was provided for the hepatitis B vaccination-
 2 specific parameter values. As the sensitivity analyses only evaluated
 3 generic assumptions across all options, no sensitivity analysis considered
 4 the impact of option-specific assumptions. Therefore little consideration
 5 was given to the possibility that the benefit-cost ratios might change in
 6 relation to each other. If one (or more) intervention could move
 7 significantly closer to another, differences between options diminish and
 8 this could be of decisional importance. As it is relatively easy to choose
 9 alternative assumptions to effect change in these benefit-cost ratios, the
 10 reasoning for choosing alternative values is important. Therefore this
 11 quick reanalysis reflects sources the authors have cited, and applies
 12 health sector specific evidence to well versed economic arguments (i.e.
 13 rising marginal cost to achieve maximum coverage) to support four
 14 cumulative analyses:

<i>For achieving more favourable benefit-cost ratios</i>	<i>For achieving less favourable benefit-cost ratios</i>
1. Used mean cost from Brenzel et al (2006) referenced in challenge paper (range \$2.02-\$2.37)	1. Doubled cost of achieving last 10%-point increase in coverage to

³ [Johns and Baltussen \(2004\)](#)^{BIB-3_1} showed that marginal costs rose by 70–100% roughly double for achieving the last 10% coverage of a hygiene outreach programme

and inflated to the publication year for Indian cost data used in base case. New cost was \$2.7 per vaccinated child.	achieve 100% ³ from \$3.6 to \$7.2 per child vaccinated for (the effective average cost increased to \$5.04 from 75–100% coverage)
2. No amendment made for avoidable mortality as assumptions already appeared favourable (future burden likely to decline given increasing hep B vaccination rates ^{and assumption of 100% efficacy})	2. Used assumptions on avoidable mortality from Brenzel et al (2006)
3. Used a slightly older coverage rate of 64% vaccine coverage from Duclos et al (2009)^{BIB-3-1} . While out of date, the% will reflect the position for some countries.	3. Assumed increase of 3% in global coverage rates since 2010.
4. Assumed benefits occurred in 30 rather than 40 years.	4. Assumed benefits occurred in 50 rather than 40 years.

1
2 Results for the final cumulative step are given in [Table 1](#). The more
3 favourable assumptions move the benefit-cost ratio from 7:1 to 9:1 and
4 13:1. The less favourable assumptions move the benefit-cost ratio from
5 7:1 to 5:1 to 4:1, and finally to 3:1, which is on a par with the generic risk
6 pill. Further investigation of the impact of alternative option-specific
7 assumptions for the four other interventions may reveal a credible
8 alternative positioning of benefit-cost ratios, both in absolute and relative
9 terms.

A

10 **Treatment of uncertainty**

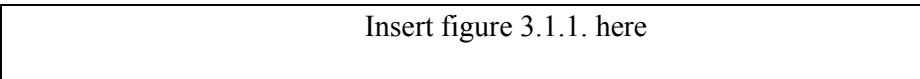

1 The challenge paper refers to uncertainty⁴ in a number of ways: the size
2 and shape of the future tobacco hazards; greater misclassification of
3 morbidity compared with mortality statistics; methodological uncertainty
4 about completeness of data, age weighting and discount rates;
5 effectiveness of interventions to prevent elevated blood pressure, blood
6 lipids, and diabetes; and adherence to the polypill. To reflect this, the
7 benefit-cost estimates are referred to as ‘indicative’ and parameters to
8 being a ‘ballpark idea’ (e.g. of the economic cost at the macro level). In
9 each case further information on these issues would reduce uncertainty
10 and provide more precise estimates.

11 The challenge paper judges that, given the “often broad ranges in
12 CE ratios, and hence in benefit-cost ratios, it makes little sense to
13 conclude with precise estimates or with attempts to quantify statistical
14 uncertainty around the point estimates”. While there may be little
15 possibility, given the uncertainties noted, of providing precise estimates,
16 the conclusion that quantification of uncertainty should therefore be

⁴ This should be distinguished from variation for which further information could not increase precision as heterogeneity in patient (e.g. age, severity of disease, health outcomes) or health system (e.g. price) characteristics refers to real differences. Jha et al mention additionally variation in prices, scale of the intervention and epidemiological environment.

1 avoided is a little hasty. Indeed, its avoidance may result in inappropriate
2 recommendations.

3 Briggs (1995) showed clearly that knowing the precision of an
4 incremental cost-effectiveness ratio can affect the decision about which
5 intervention to implement and indicated that choices may differ from that
6 implied by point estimates alone. For example, in Figure 1 a decision
7 maker with a willingness to pay of £10,000 per quality adjusted life year
8 (QALY) might justifiably prefer intervention C above intervention A or
9 B, because it is a more precise estimate of the incremental cost-
10 effectiveness ratio even though the point estimate of the cost per QALY
11 is higher. Since this work, much progress has been made in defining,
12 measuring and interpreting uncertainty in the context of using economic
13 evaluation to aid both investment adoption decisions as well as defining
14 the need for further research. It has also led to much greater emphasis on
15 the systematic search and review of evidence, as well as methods for
16 eliciting expert opinion and analysis of evidence that influences the
17 choice of parameter estimates in economic evaluations of health
18 interventions (Griffin S and Claxton C 2011).

19  Insert figure 3.1.1. here

20 As uncertainty in both costs and effects can vary by intervention
21 (e.g. [Sassi et al, 2009^{BIB-3-1}](#)) it is possible that the benefit-cost ratios
22 presented in the challenge paper could be differentially affected by

1 uncertainty. While it is unusual for uncertainty to be reflected in benefit-
2 cost cost ratios, the analysis of benefit by Jha and colleagues relies
3 heavily on the value of DALYs averted and is not intrinsically different
4 from the majority of economic evaluations presented in the health sector.
5 Therefore analysis of uncertainty could be expected and decisions made
6 without reference to it could badly mislead understanding of the
7 likelihood of future costs and benefits.

A

8 **Evidence to substantiate, refute and counter the priorities**
9 **recommended**

10 Two exercises designed to help encourage and guide investment
11 decisions for controlling chronic disease have recently been published.
12 The WHO produced three related reports (WHO 2011a, 2011b, 2011c)
13 outlining the ‘best buys’ for controlling chronic disease and detailed the
14 costs of scaling up the proposed interventions (to a level where 80%
15 coverage is achieved within 15 years). A ‘best buy’ was considered to be
16 an intervention that averts one DALY for less than the average annual
17 income per capita but is also considered “cheap, feasible and culturally
18 acceptable to implement”⁵.

⁵ This contrasts with ‘good buys’ which are other interventions that may cost more or generate less health gain but are still considered to provide good value for money.

1 As Jha et al state, all five interventions proposed are, at least
2 partially, reflected in the listing of ‘best buys’. While this is important
3 corroboration of the value of their investment proposal, there are two
4 important caveats to accepting this as sufficient validation. First, further
5 inspection of the ‘best buys’ indicates that several other interventions
6 could have been selected, but the challenge paper is silent on both their
7 non-selection and the reasons for their non-selection⁶. The missing
8 interventions include entire areas, such as controlling alcohol,⁷ as well as
9 competing and complementary interventions for the risk factors
10 addressed⁸. Secondly, the reference point for the WHO reports was a

⁶ The need to select is, however, clear as the total cost of the package was expected to be \$170bn with an average annual cost of \$11.4 billion per year.

⁷ This included restricting access, enforce bans on advertising, raising taxes on alcohol, monitoring, advocacy/support. The authors explained (personal communication) that, while excess deaths in Russia can be linked clearly to binge drinking, the net effect in other populations is less clear. However, this decision also appears to be another impact of linking morbidity only to cases of mortality.

⁸ For diet, these include promoting public awareness about diet and physical activity, replacing trans fat with polyunsaturated fat. For tobacco it includes smoke-free indoor workplaces and public places,

1 focus on “four diseases; cardiovascular disease, cancer, diabetes and
2 chronic respiratory disease....(which are) largely caused by four shared
3 behavioural risk factors; tobacco use, harmful alcohol use, physical
4 inactivity, and unhealthy diet” (WHO 2011c, *p10*). Therefore,
5 confirmation is less convincing as a case for accepting that the best
6 investments have been presented in the challenge paper, as good
7 alternatives may exist outside of these disease areas.

8 A second exercise conducted by WHO focussed on the cost-
9 effectiveness of over 500 single or combined interventions for the
10 prevention and control of non-communicable diseases and injuries in
11 countries in sub-Saharan Africa and South East Asia that have high adult
12 and child mortality ([Chisholm and Saxena 2012^{BIB-3_1}](#), [Chisholm et al
13 2012^{BIB-3_1}](#), [Ginsberg et al 2012^{BIB-3_1}](#), [Ortegón, Lim, Chisholm and
14 Mendis 2012^{BIB-3_1}](#), [Ortegon et al 2012^{BIB-3_1}](#), [Baltussen and Smith
15 2012^{BIB-3_1}](#)). This is interesting for a number of reasons: the analysis
16 extends beyond the disease areas of the challenge paper and the ‘best
17 buy’ analysis, including road traffic injuries, mental health, and sensory

health information and warning, bans on advertising, promotion and
sponsorship. Other possibilities to reduce CVD and cancer risks not
presented include; screening in primary care for CVD risk, counselling
and multi-drug therapy for individuals with >30 CVD risk, prevention
of cervical cancer through screening and lesion removal.

1 loss disorders; it provides a more accountable and direct comparison of a
2 broader range of interventions; and, for the interventions that are not
3 dominated⁹ (within disease clusters), a probabilistic cost-effectiveness
4 analysis indicates some degree of the uncertainty. However, there are still
5 limitations with using this analysis as a full critique or validation of
6 investment options presented in the challenge paper. For example, the
7 analysis is restricted to two WHO regions, one intervention proposed by
8 Jha et al is excluded entirely (hepatitis B vaccination¹⁰), and the drug
9 based interventions proposed in the challenge paper are potentially
10 grouped slightly differently¹¹.

11

Insert table 3.1.2 here

12 The second exercise, led by Chisholm, provides strong support for
13 increasing tobacco tax as it is a particularly cost-effective intervention for
14 both WHO regions (see [Table 2](#)). However, salt reduction and all salt

⁹ An intervention is ‘dominated’ if it is more costly and/or less effective than other (more efficient) interventions

¹⁰ Because treatment of liver disease was considered not to have strong evidence of effectiveness and aspects of prevention of hepatitis B and cirrhosis were ‘covered’ already in some of the alcohol interventions evaluated ([Ginsberg et al 2012^{BIB-3_1}](#)).

¹¹ This isn’t entirely clear as the WHO based analysis does allow combinations of therapies.

1 based interventions were dominated by other options (within their
2 disease/risk factor cluster), as was treatment of AMI with aspirin, ace
3 inhibitor and beta blockers and all of the, drug therapy based,
4 secondary/tertiary prevention of myocardial infarction. This indicates that
5 other interventions could achieve greater DALY gain per \$ spent.

6

Insert table 3.1.3 here

7 [Chisholm et al \(2012\)](#)^{BIB-3_1} note that, compared with all other
8 interventions for controlling chronic disease, “antibiotic treatment of
9 chronic otitis media (a persistent inflammation of the middle ear) is the
10 most cost-effective intervention in the two regions (<\$Int100/DALY
11 saved), while extraction of cataracts and proactive screening for hearing
12 loss are among the biggest contributors to population health gain”. The
13 detailed results are provided in [Table 3](#) and it can be seen that, even in
14 comparison with tax increases for tobacco, these interventions are more
15 cost-effective. However, with a population of 2 million needing cataract
16 surgery in Africa and 4.2 million in South East Asia (Baltussen and
17 Smith), the annual treatment is unlikely make a significant dent in the
18 hypothetical budget facing the Copenhagen Consensus Panel given that
19 the number of interventions selected are restricted to five. However, this
20 is unlikely to be the case for an intervention such as treatment based on
21 absolute risk of a cardiovascular event in next 10 years with statin,
22 diuretic, β blocker, and aspirin for cardiovascular risk of 5% (CVD-11).

1 In this case, the annual DALYs saved per million population is 3,163 at a
2 cost of Int\$ 0.33 per capita and both an average and incremental cost-
3 effectiveness ratio of Int\$104 per DALY averted.

A

4 **Conclusion**

5 Whether an additional investment of upto \$75 billion should comprise the
6 five interventions proposed by Jha and colleagues is questionable. The
7 initial filtering through calculations of disease burden combined with a
8 lack accounting for uncertainty and a sensitivity analysis that did not
9 question the relative rankings of interventions suggests that the best buys
10 are unlikely to be presented. Other evidence suggests that alternative
11 interventions could indeed provide a better return on investment.
12 Examples include cataract surgery, antibiotic treatment for otitis media
13 and primary prevention of CVD. However, the cost-effectiveness analysis
14 on which the latter suggestions are made do not account for the level of
15 health system support needed. Jha et al do discuss this at length and it
16 would have been interesting to see both a quantification of health system
17 support needed for the proposed interventions in the challenge paper as
18 well as understanding why this would not support the range of alternative
19 interventions highlighted in the recent series of papers in the British
20 Medical Journal.

1 **Table 3.1.1 Replication and extension of Jha et al estimate for hepatitis B**2 **vaccination**

3

	Jha et al estimates	Less favourable assumptions	More favourable assumptions
Birth cohort	136,000,000	136,000,000	136,000,000
Average cost vaccination	3.6	4.6	2.7
Annual cost of vaccinating all children	489,600,000	625,600,000	367,200,000
Proportion vaccinated	0.75	0.64	0.75
New proportion to be vaccinated	1	1	1
1% linear cost	4,896,000	6,256,000	3,672,000
Extra% coverage re expected cost	122,400,000	225,216,000	91,800,000
Deaths from Hep B	600,000	1,400,000	600,000
Deaths assumed potentially savable from HBV given current and future vaccination coverage	150,000	176,400	150,000
DALYs lost per death	20	20	20
DALYs	3,000,000	3,528,000	3,000,000
Value of death/DALY averted	1,000	1,000	1,000
Value of death averted	150,000,000	176,400,000	150,000,000

Value of DALY averted	3,000,000,000	3,528,000,000	3,000,000,000
Undiscounted B:C ratio (death)	1	1	2
Undiscounted B:C ratio (DALYs)	25	16	33
discounted deaths (3%, 40yrs)	45,179	39,360	60,985
discounted DALYs	903,583	787,203	1,219,709
Discounted value deaths	45,179,132	39,360,160	60,985,449
Discounted value DALYs	903,582,636	787,203,205	1,219,708,979
Discounted benefit-cost ratio deaths	0	0	1
Discounted benefit-cost ratio DALYs	7	3	13
