Abstract

We present a comprehensive approach to address three challenging problems in face recognition: modelling faces across multi-views, extracting the non-linear discriminating features, and recognising moving faces dynamically in image sequences. A multi-view dynamic face model is designed to extract the *shape-and-pose-free* facial texture patterns. Kernel Discriminant Analysis, which employs the kernel technique to perform Linear Discriminant Analysis in a high-dimensional feature space, is developed to extract the significant non-linear features which maximise the between-class variance and minimise the within-class variance. Finally, an *identity surface* based face recognition is performed dynamically from video input by matching object and model trajectories.

1 Introduction

Face recognition has been of considerable interest over the past decade. Various approaches such as Eigenfaces [16], Elastic Graph model [9], Linear Object Classes [19], Active Shape Models (ASMs) [3] and Active Appearance Models (AAMs) [2] have been proposed to address this problem. It is important to point out that most of the previous work in face recognition is mainly concerned with frontal view or near frontal views. Due to the severe non-linearity caused by rotation in depth, self-occlusion, self-shading and illumination change, recognising faces with large pose variation is more challenging than that at a fixed view, e.g. frontal view.

Extracting the discriminating features, which maximise the between-class variance and minimise the within-class variance, is crucial to face recognition, especially when faces are undergoing large pose variation. Principal Component Analysis (PCA), also known as eigenface method, has been widely adopted in this area [14, 16]. However, it is worth noting that the features extracted by PCA are actually “global” features for all face classes, thus they are not necessarily representative for discriminating one face class from others. Linear Discriminant Analysis (LDA), which seeks to find a linear transformation by maximising the between-class variance and minimising the within-class variance, proved to be a more suitable technique for classification [5, 15]. Although LDA can provide a significant discriminating improvement to the task of face recognition, it is still a linear technique in nature. When severe non-linearity is involved, this method is intrinsically poor. Another shortcoming of LDA lies in the fact that the number of basis vectors is limited by the number of face classes, therefore it would be less representative when a small set of subjects is concerned. To extract the non-linear principal components, Kernel PCA (KPCA) was developed [13, 12]. However, as with PCA, KPCA captures the *overall* variance of all patterns which are inadequate for discriminating purposes.

Another limitation of the previous studies is that the methodology adopted for recognition is largely based on matching static face images. Psychology and physiology research depicts that the human vision system's ability to recognise animated faces is better than that on randomly ordered still face images (i.e. the same set of images, but displayed in random order without the temporal context of moving faces) [8, 1]. For computer vision systems, although some work has been reported [7, 4, 6], the problem of recognising the dynamics of human faces in a spatio-temporal context remains largely unresolved.

In this work, we present a comprehensive approach to address the three challenging problems in face recognition stated above. A multi-view dynamic face model is designed to extract the *shape-and-pose-free* facial texture patterns for accurate across-view registration. Kernel Discriminant Analysis (KDA), a kernel based technique, is developed to compute the non-linear discriminating basis vectors. Finally face recognition is performed dynamically by matching an object trajectory tracked from a video input with model trajectories synthesised on *identity surfaces*.

2 Kernel Discriminant Analysis

As stated in the previous section, both PCA and LDA are limited to linear problems, and KPCA is designed to deal with the *overall* rather than the *discriminating* variance. In this work, Kernel Discriminant Analysis, a nonlinear discriminating approach based on the kernel technique [18] is developed for extracting the nonlinear discriminating features.

The underlying principle of KDA is described as follows: For a set of training patterns $\{\mathbf{x}\}$ which are categorised into C classes, ϕ is defined as a non-linear map from the input space to a high-dimensional feature space. Then by performing LDA in the feature space, one can obtain a non-linear representation in the original input space. However, computing ϕ explicitly may be problematic or even impossible. By employing a kernel function

$$k(\mathbf{x}, \mathbf{y}) = (\phi(\mathbf{x}) \cdot \phi(\mathbf{y})) \quad (1)$$

the inner product of two vectors \mathbf{x} and \mathbf{y} in the feature space can be calculated directly in the input space.

The problem can be finally formulated as an eigen-decomposition problem

$$\mathbf{A}\boldsymbol{\alpha} = \lambda\boldsymbol{\alpha} \quad (2)$$

The $N \times N$ matrix \mathbf{A} is defined as

$$\mathbf{A} = \left(\sum_{c=1}^C \frac{1}{N_c} \mathbf{K}_c \mathbf{K}_c^T \right)^{-1} \left(\sum_{c=1}^C \frac{1}{N_c^2} \mathbf{K}_c \mathbf{1}_{N_c} \mathbf{K}_c^T \right) \quad (3)$$

where N is the number of all training patterns, N_c is the number of patterns in class c , $(\mathbf{K}_c)_{ij} := k(\mathbf{x}_i \cdot \mathbf{x}_j)$ is an $N \times N_c$ kernel matrix, and $(\mathbf{1}_{N_c})_{ij} := 1$ is an $N_c \times N_c$ matrix. More details of the underlying algorithm are available in [10].

For a new pattern \mathbf{x} , one can calculate its projection onto a KDA basis vector \mathbf{v} in the high-dimensional feature space by

$$(\phi(\mathbf{x}) \cdot \mathbf{v}) = \boldsymbol{\alpha}^T \mathbf{k}_x \quad (4)$$

where $\mathbf{k}_x = (k(\mathbf{x}, \mathbf{x}_1), k(\mathbf{x}, \mathbf{x}_2), \dots, k(\mathbf{x}, \mathbf{x}_N))^T$. Constructing the eigen matrix $\mathbf{U} = [\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \dots, \boldsymbol{\alpha}_M]$ from the first M significant eigenvectors of \mathbf{A} , the projection of \mathbf{x} in the M -dimensional KDA space is given by

$$\mathbf{y} = \mathbf{U}^T \mathbf{k}_x \quad (5)$$

We use a “toy” problem to illustrate the characteristics of KDA as shown in Figure 1. Two classes of patterns, denoted by circles and crosses respectively, have a significant non-linear distribution. We try to separate them with a *one dimensional* decision boundary of PCA, LDA, KPCA or KDA. The upper row shows the patterns and the discriminating curves computed by the four different methods. The lower row illustrates the intensity values of the one-dimensional features computed from PCA, LDA, KPCA and KDA. It can be seen clearly that PCA and LDA are incapable of providing correct classification because of their linear nature. Neither does KPCA do so since it is designed to extract the overall rather than the discriminating variance although it is nonlinear in principle. KDA gives the correct classification boundary: the discriminating curve accurately separates the two classes of patterns, and the feature intensity correctly reflects the actual pattern distribution.

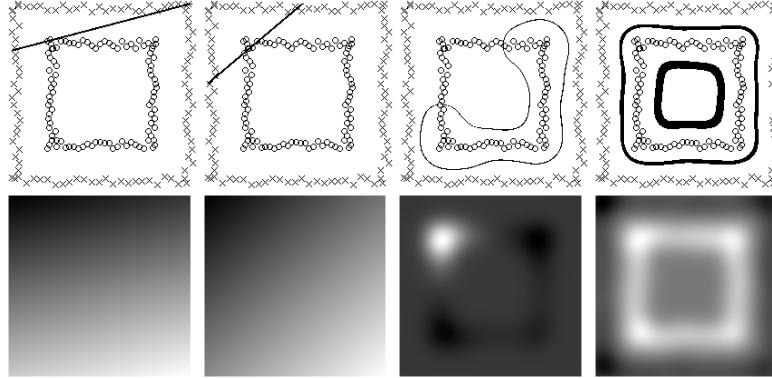

Figure 1: Solving a nonlinear classification problem with, from left to right, PCA, LDA, KPCA and KDA.

3 Multi-View Dynamic Face Model

Due to the severe non-linearity caused by rotation in depth, self-occlusion, self-shading and illumination change, modelling the appearance of faces across multiple views is much more challenging than that from a fixed, e.g. frontal, view. Another significant difficulty for multi-view face recognition comes from the fact that the appearances of different people from the same view are often more similar than those of the same person from different views.

A multi-view dynamic face model, which consists of a sparse 3D Point Distribution Model (PDM) [3], a *shape-and-pose-free* texture model, and an affine geometrical model, is developed in this work. This model is extended from AAMs [2], but is distinguished from AAMs by: (1) a 3D shape model is constructed from 2D images, and (2) the texture model is built from *shape-and-pose-free* texture patterns.

The 3D shape vector of a face is estimated from a set of 2D face images in different views, i.e. given a set of 2D face images with known pose and 2D positions of the landmarks, the 3D shape vector can be estimated using linear regression. To decouple the covariance between shape and texture, a face image fitted by the shape model is warped to the mean shape at frontal view (with 0° in both tilt and yaw), obtaining a *shape-and-pose-free* texture pattern. This is implemented by forming a triangulation from the landmarks and employing a piece-wise affine transformation between each triangle pair. By warping to the mean shape, one obtains the shape-free texture of the given face image. Furthermore, by warping to the frontal view, a pose-free texture representation is achieved. We applied PCA to the 3D shape patterns and *shape-and-pose-free* texture patterns respectively to obtain a low dimensional statistical model. Figure 2 shows the sample face

images used to construct the model, the landmarks labelled on each image, the 3D shape estimated from these labelled face images, and the extracted *shape-and-pose-free* texture patterns.

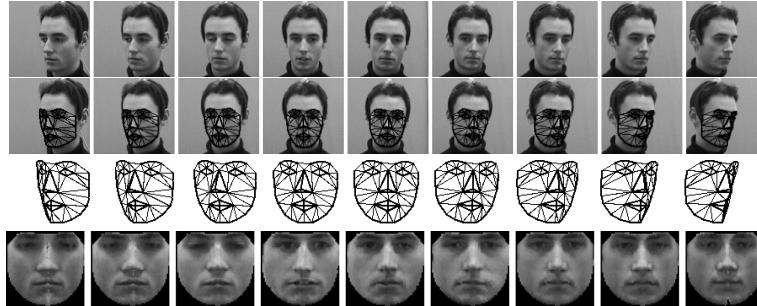

Figure 2: Multi-view dynamic face model. From top to bottom are sample training face images, the landmarks labelled on the images, the estimated 3D shape rotating from -40° to $+40^\circ$ in yaw and with tilt fixed on 0° , and the extracted *shape-and-pose-free* texture patterns.

Based on the analysis above, a face pattern can be represented in the following way. First, the 3D shape model is fitted to a given image or video sequence containing faces. Then the face texture is warped onto the mean shape of the 3D PDM model in frontal view. Finally, by adding parameters controlling pose, shift and scale, the complete parameter set of the dynamic model for a given face pattern is $\mathbf{c} = (\mathbf{s}, \mathbf{t}, \alpha, \beta, dx, dy, r)^\top$ where \mathbf{s} is the shape parameter, \mathbf{t} is the texture parameter, (α, β) is pose in tilt and yaw, (dx, dy) is the translation of the centroid of the face, and r is its scale. More details of model construction and fitting are described in [11].

The *shape-and-pose-free* texture patterns obtained from model fitting are adopted for face recognition. In our experiments, we also tried to use the shape patterns for recognition, however, the performance was not as good as that of using textures.

4 Extracting the Non-linear Discriminating Features of Multi-view Face Patterns

If we ignore the influence of illumination and expression, there are mainly two kinds of variance involved for multi-view face recognition, variance from different subjects (between-class variance) and variance from pose change (within-class variance). Under these circumstances, the task of face recognition is to emphasise the former and suppress the latter. Although the within-class variance of the *shape-and-pose-free* facial texture patterns has been reduced from their original form, the underlying discriminating features for different face classes have not been represented explicitly. Therefore such a representation in itself may not be efficient for recognition. This situation is illustrated in Figure 3(a) where the *shape-and-texture-free* texture patterns of four face classes are represented by PCA, the widely used method in face recognition. It is noted that the variance from different face classes is not efficiently separated from that for pose change, or more precisely, the former is even overshadowed by the latter.

We applied KDA to the same set of facial texture patterns. The distribution of the KDA patterns are shown in Figure 3(b). Compared to that of the PCA patterns, the improvement on class separability is significant. In this work, we adopt the KDA vectors of facial texture patterns to represent faces.

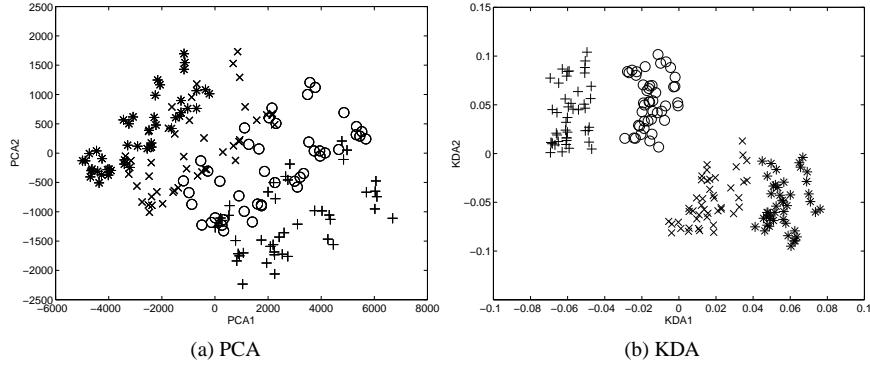

Figure 3: Distribution of PCA/KDA facial texture patterns.

5 Recognising Multi-view Faces Using Identity Surfaces

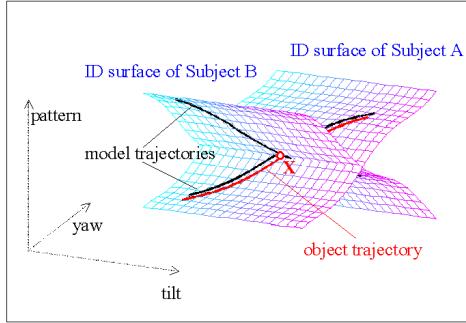

Figure 4: Identity surfaces for dynamic face recognition.

The traditional techniques for face recognition include computing the Euclidean or Mahalanobis distance to a face template and estimating the density of patterns using multi-modal models. However, the problem of *multi-view* face recognition can be solved more efficiently if the pose information is available. Based on this idea, we propose an approach to multi-view face recognition by constructing *identity surfaces* in a discriminating feature space.

subject to be recognised is represented by a unique hyper surface based on pose information. In other words, the two basis coordinates stand for the head pose: tilt and yaw, and the other coordinates are used to represent the discriminating feature patterns of faces. For each pair of tilt and yaw, there is one unique “point” for a face class. The distribution of all these “points” of a same face class forms a hyper surface in this feature space. We call this surface an *identity surface*.

5.1 Synthesising Identity Surfaces

We propose to synthesise the *identity surface* of a subject from a small sample of face patterns which sparsely cover the view sphere. The basic idea is to approximate the *identity surface* using a set of N_p planes separated by a number of N_v predefined views. The problem can be formally defined as follows:

Suppose x, y are tilt and yaw respectively, \mathbf{z} is the discriminating feature vector of a face pattern, i.e. the KDA vector. $(x_{01}, y_{01}), (x_{02}, y_{02}), \dots, (x_{0N_v}, y_{0N_v})$ are predefined views which separate the view plane into N_p pieces. On each of these N_p pieces, the *identity surface* is approximated by a plane

$$\mathbf{z} = \mathbf{a}x + \mathbf{b}y + \mathbf{c} \quad (6)$$

Suppose the M_i sample patterns covered by the i th plane are $(x_{i1}, y_{i1}, \mathbf{z}_{i1}), (x_{i2}, y_{i2}, \mathbf{z}_{i2}), \dots, (x_{iM_i}, y_{iM_i}, \mathbf{z}_{iM_i})$, then one minimises

$$Q = \sum_i^{N_p} \sum_m^{M_i} \|\mathbf{a}_i x_{im} + \mathbf{b}_i y_{im} + \mathbf{c}_i - \mathbf{z}_{im}\|^2 \quad (7)$$

$$\begin{aligned} \text{subject to : } & \mathbf{a}_i x_{0k} + \mathbf{b}_i y_{0k} + \mathbf{c}_i = \mathbf{a}_j x_{0k} + \mathbf{b}_j y_{0k} + \mathbf{c}_j \\ & k = 0, 1, \dots, N_v, \\ & \text{planes } i, j \text{ intersect at } (x_{0k}, y_{0k}). \end{aligned} \quad (8)$$

This is a quadratic optimisation problem which can be solved using the interior point method [17].

5.2 Dynamic Face Recognition by Trajectory Matching

For an unknown face pattern (x, y, \mathbf{z}_0) where \mathbf{z}_0 is the KDA vector and x, y are the pose in tilt and yaw, one can classify this pattern into one of the known face classes by computing the distance to each of the *identity surfaces* as the Euclidean distance ¹ between \mathbf{z}_0 and the corresponding point on the *identity surface* \mathbf{z}

$$d = \|\mathbf{z}_0 - \mathbf{z}\| \quad (9)$$

where \mathbf{z} is given by (6).

As shown in Figure 4, when a face is tracked continuously in a video sequence using the multi-view dynamic face model described in Section 3, an object trajectory is obtained by projecting the face patterns into the KDA feature space. On the other hand, according to the pose information of the face patterns, one can build the model trajectory on the *identity surface* of each subject using the same pose information and temporal order of the object trajectory. Those two kinds of trajectories, i.e. object and model trajectories, encode the spatio-temporal information of the tracked face. And finally, the recognition problem can be solved by matching the object trajectory to a set of model trajectories. A preliminary realisation of trajectory matching is implemented by computing the trajectory distances up to time slice t

$$d_m = \sum_{i=1}^t w_i d_{mi} \quad (10)$$

where d_{mi} , the pattern distance between the face pattern captured in the i th frame and the *identity surface* of the m th subject, is computed from (9), and w_i is the weight on this distance. Finally, the optimal m with minimum d_m is chosen as the recognition result.

6 Experiments

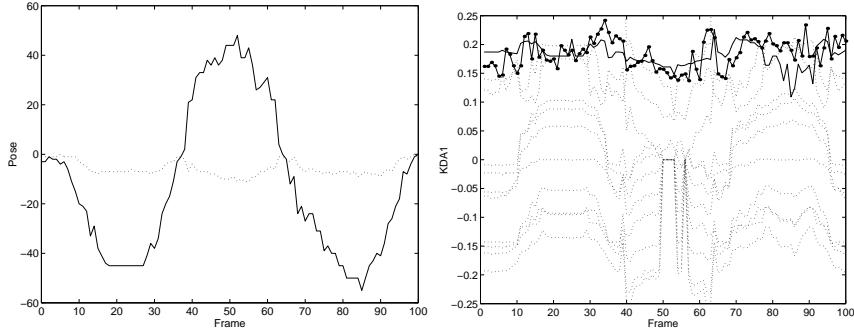

We demonstrate the performance of this approach on a small scale multi-view face recognition problem. Twelve sequences, one of each subject, were used as training sequences. The sequence length varies from 40 to 140 frames. We randomly selected 180 images (15 images of each subject) to train KDA. Then recognition was performed on new test sequences of these subjects.

¹It is important to note that Euclidean distance is more appropriate for KDA and LDA while Mahalanobis distance is more efficient for PCA and KPCA since the discriminating features are extracted in the former case and the general variation is concerned in the latter.

Figure 5 shows the results on one of the test sequences. It is noted that a more robust performance is achieved when recognition is carried out using the trajectory distances which include the accumulated evidence over time, although the pattern distances in each individual frame already provides good recognition accuracy on a frame by frame basis.

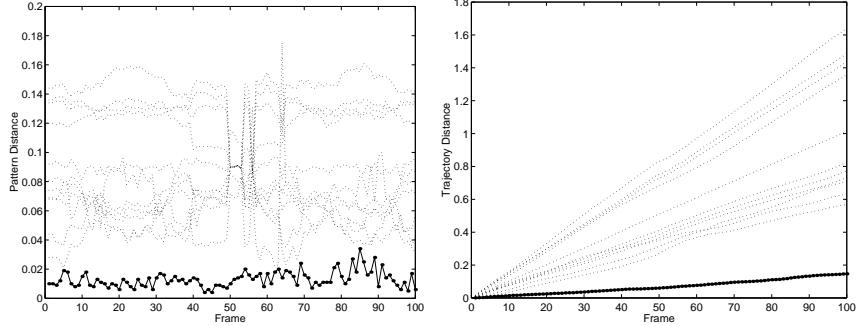

(a) Sample frames, fitted 3D shape patterns, and the *shape-and-pose-free* texture patterns.

(b) Pose in tilt (dotted) and yaw (solid).

(c) Object and model trajectories.

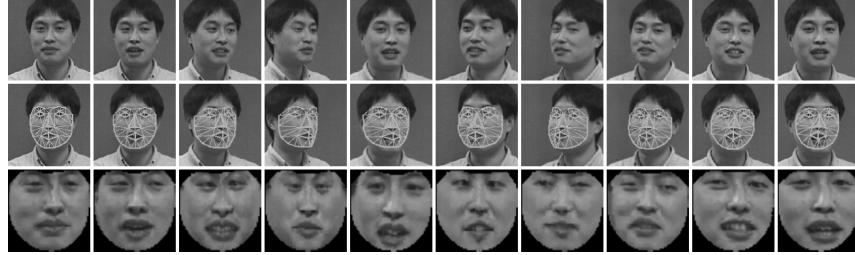

(d) Pattern distances.

(e) Trajectory distances.

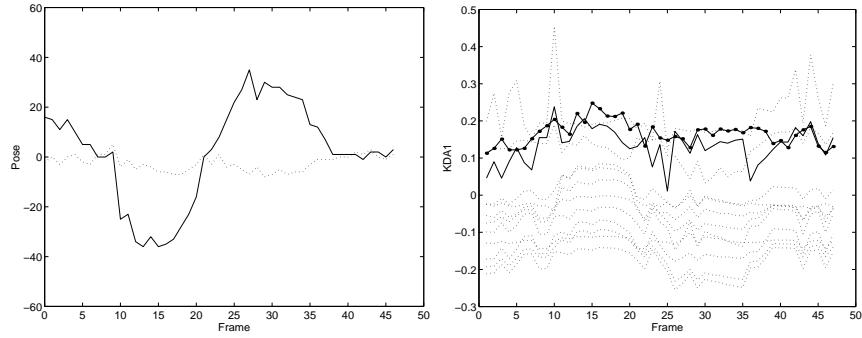

Figure 5: Video-based multi-view face recognition. (c) shows the object trajectory (solid line with dots) and model trajectories in the first KDA dimension where the model trajectory from the ground-truth subject is highlighted with solid line. It is noted from (d) and (e) that the pattern distances can give an accurate recognition result; however, the trajectory distances provide a more robust performance, especially its accumulated effects (i.e. discriminating ability) over time.

Figure 6 shows the results on another sequence where the face is undergoing significant expression change. Since all the training face images are taken in neutral expression, the results of model fitting is not as good as those in Figure 5. Also, the pattern distance from an individual frame gives the wrong recognition result in a few frames. However,

it is important to point out that the trajectory distance still provides a robust and accurate recognition.

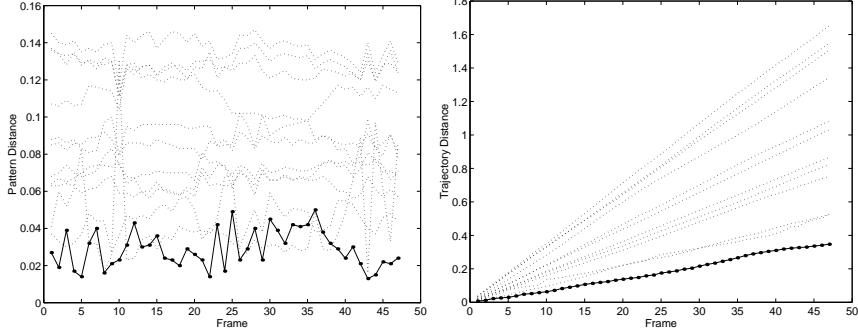

(a) Sample frames, fitted 3D shape patterns, and warped texture patterns.

(b) Pose in tilt (dotted) and yaw (solid).

(c) Object and model trajectories.

(d) Pattern distances.

(e) Trajectory distances.

Figure 6: Face recognition on a face sequence with significant expression change. The pattern distance is less reliable for a few frames, however, the trajectory distance still provides a robust and accurate recognition.

To compare with KDA, we applied the PCA, KPCA, and LDA techniques using the same set of face patterns. To make the results of different representations comparable, we define the following criterion

$$d' = \frac{1}{N} \sum_{i=1}^N \frac{C \cdot d_{i0}}{\sum_{j=1}^C d_{ij}} \quad (11)$$

where C is the number of face classes, N is the total number of test face patterns, d_{ij}

is the pattern distance between the i th test pattern and the j th face class, and d_{i0} is the pattern distance between the i th test pattern and the ground-truth face class.

Criterion d' can be interpreted as a summation of normalised pattern distances to their ground-truth face class. The smaller the d' , the more reliable the classification. Figure 7 shows the values of d' for different representations, PCA, KPCA, LDA and KDA, with respect to the dimension of the feature spaces. The results indicate that KDA gives the most reliable classification performance.

The recognition accuracies with respect to the dimension of feature spaces are shown in Figure 8. It is interesting to note that the KDA features are very efficient. A 93.9% recognition accuracy was achieved when the dimension of the KDA vector was only 2. It is also observed that, for the small scale problem (12 subjects), all the method except for KPCA achieved a 100% recognition accuracy when the dimension of features is not less than 6. We will investigate how these techniques perform on large scale problems in future work.

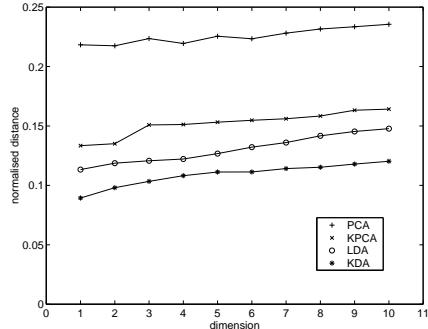

Figure 7: Recognition reliability

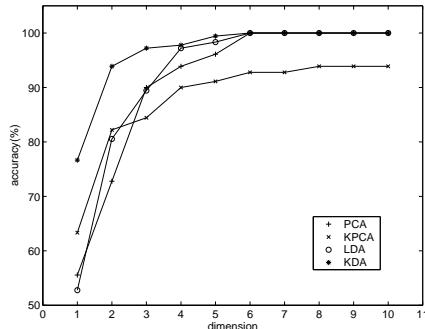

Figure 8: Recognition accuracy.

7 Conclusions

In this paper, we have presented a comprehensive approach to multi-view dynamic face recognition. This approach is designed to address three challenging problems: modelling faces across multi-views, extracting non-linear discriminating features, and recognising moving faces dynamically in image sequences.

To model faces with large pose variation, we developed a dynamic face model, which includes a 3D PDM, a *shape-and-pose-free* texture model, and an affine geometrical model. By representing faces with the *shape-and-pose-free* texture patterns, the variance from pose change is suppressed.

PCA, LDA and KPCA have been widely used in face recognition. But PCA and LDA are limited to the linear applications while KPCA intends to capture the *overall* rather than the *discriminating* variance of patterns even though it is non-linear. To efficiently extract the discriminating features of multi-class patterns with severe non-linearity, KDA, which implicitly performs LDA in a non-linear feature space through a kernel function, is developed in this work. When applying KDA to the *shape-and-pose-free* texture patterns, the variance from pose change is further reduced and the variance from different identities is emphasised.

Instead of matching templates or estimating multi-modal density, the *identity surfaces* of face classes are constructed in a discriminating feature space. Recognition is then performed dynamically by matching an object trajectory tracked from a video input with a set of model trajectories synthesised on the *identity surfaces*. Experimental results depict that this approach provides robust and accurate recognition.
