Abstract

Objective To evaluate current risk models and scores for type 2 diabetes and inform selection and implementation of these in practice.

Design Systematic review using standard (quantitative) and realist (mainly qualitative) methodology.

Inclusion criteria Papers in any language describing the development or external validation, or both, of models and scores to predict the risk of an adult developing type 2 diabetes.

Data sources Medline, PreMedline, Embase, and Cochrane databases were searched. Included studies were citation tracked in Google Scholar to identify follow-on studies of usability or impact.

Data extraction Data were extracted on statistical properties of models, details of internal or external validation, and use of risk scores beyond the studies that developed them. Quantitative data were tabulated to compare model components and statistical properties. Qualitative data were analysed thematically to identify mechanisms by which use of the risk model or score might improve patient outcomes.

Results 8864 titles were scanned, 115 full text papers considered, and 43 papers included in the final sample. These described the prospective development or validation, or both, of 145 risk prediction models and scores, 94 of which were studied in detail here. They had been tested on 6.88 million participants followed for up to 28 years. Heterogeneity of primary studies precluded meta-analysis. Some but not all risk models or scores had robust statistical properties (for example, good discrimination and calibration) and had been externally validated on a different population. Genetic markers added nothing to models over clinical and sociodemographic factors. Most authors described their score as "simple" or "easily implemented," although few were specific about the intended users and under what circumstances. Ten mechanisms were identified by which measuring diabetes risk might improve outcomes. Follow-on studies that applied a risk score as part of an intervention aimed at reducing actual risk in people were sparse.

Conclusion Much work has been done to develop diabetes risk models and scores, but most are rarely used because they require tests not routinely available or they were developed without a specific user or clear use in mind. Encouragingly, recent research has begun to tackle usability and the impact of diabetes risk scores. Two promising areas for further research are interventions that prompt lay people to check their own diabetes risk and use of risk scores on population datasets to identify high risk "hotspots" for targeted public health interventions.

Introduction

The prevalence of diabetes is rising rapidly throughout the world.1 By 2010 its prevalence in the adult populations of the United Kingdom, the United States, mainland China, and the United Arab Emirates had exceeded 7%,² 11%,³ 15%,⁴ and 17%,⁵ respectively. Americans born in 2000 or later have a lifetime risk of more than one in three of developing diabetes.⁶ Type 2 diabetes (which accounts for over 95% of diabetes worldwide) results from a complex gene-environment interaction for which several risk factors, such as age, sex, ethnicity, family history, obesity, and hypertension, are well documented. The precise interaction of these and other risk factors with one another is, however, a complex process that varies both within and across populations.⁷⁻¹¹ Epidemiologists and statisticians are striving to produce weighted models that can be presented as scores to reflect this complexity but which at the same time are perceived as sufficiently simple, plausible, affordable, and widely implementable in clinical practice.¹²

Cohort studies have shown that early detection of established diabetes improves outcome, although the evidence base for screening the entire population is weak.^{14 15} The proportion of cases of incident type 2 diabetes in people with impaired glucose tolerance or impaired fasting glucose levels was reduced in landmark trials from China,¹⁶ Finland,¹⁷ and the United States¹⁸ by up to 33%, 50%, and 58%, respectively, through lifestyle

changes (increased exercise, weight loss) or pharmacotherapy, or both, although changes may be more modest in a non-trial population. Some have argued that because combining known risk factors predicts incident diabetes at least as effectively as impaired glucose metabolism, a diabetes risk score may be a better and more practical means of identifying people for preventive interventions than either a glucose tolerance test or a fasting blood glucose level.¹⁹ Others favour targeting the assessment of diabetes risk in those with established impaired glucose metabolism on the basis that interventions in this group are particularly effective.²⁰

Risk models and scores first emerged for cardiovascular disease, and these are widely used in clinical and public health practice. In the United Kingdom, for example, all electronic patient record systems in general practice offer the facility to calculate the Framingham score, a patient's risk of a cardiovascular event within 10 years. This risk score features in many guidelines and decision pathways (such as the cut-off for statin therapy²¹), and general practitioners receive financial rewards for calculating it.²² In contrast, although numerous models and scores have been developed for diabetes risk, we found limited evidence for use of these as part of a formal health policy, guideline, or incentive scheme for practitioners in any country (one Australian scheme incentivises general practitioners' measurement of the risk of diabetes in adults aged 40-49²³). This is perhaps surprising, given that morbidity and mortality from cardiovascular disease has been decreasing in many countries since the 1970s,²⁴ whereas those from diabetes continue to increase.3

A diabetes risk score is an example of a prognostic model.²⁵ Such scores should ideally be developed by taking a large, age defined population cohort of people without diabetes, measuring baseline risk factors, and following the cohort for a sufficiently long time to see who develops diabetes.²⁶ Although prospective longitudinal designs in specially assembled cohorts are expensive, difficult, and time consuming to execute, cross sectional designs in which risk factors are measured in a population including people both with and without diabetes are methodologically inferior. They use prevalence as a proxy for incidence and conflate characteristics of people with diabetes with risk factors in those without diabetes, and thus are incapable of showing that a putative risk factor predated the development of diabetes. In practice, researchers tend to take one of two approaches: they either study a cohort of people without diabetes, which was assembled some years previously with relevant baseline metrics for some other purpose (for example, the British Regional Heart Study²⁷), or they analyse routinely available data, such as electronic patient records.⁸ Both approaches are potentially susceptible to bias.

Some diabetes risk scores are intended to be self administered using questions such as "have you ever been told you have high blood pressure?" Scores that rely entirely on such questions may be hosted on the internet (see for example www.diabetes. org.uk/riskscore). Some researchers have used self completion postal questionnaires as the first part of a stepwise detection programme.²⁸ To the extent that these instruments are valid, they can identify two types of people: those who already have diabetes whether or not they know it (hence the questionnaire may serve as a self administered screening tool for undiagnosed diabetes) and those at high risk of developing diabetes-that is, it may also serve as a prediction tool for future diabetes. Prevalence rates for diabetes derived from self assessment studies thus cannot be compared directly with the rate of incident diabetes in a prospective longitudinal sample from which those testing positive for diabetes at baseline have been excluded.

A good risk score is usually defined as one that accurately estimates individuals' risk-that is, predictions based on the score closely match what is observed (calibration); the score distinguishes reliably between high risk people, who are likely to go on to develop the condition, and low risk people, who are less likely to develop the condition (discrimination); and it performs well in new populations (generalisability). Validating a risk model or score means testing its calibration and discrimination either internally (by splitting the original sample, developing the score on one part and testing it on another), temporally (re-running the score on the same or a similar sample after a time period), or, preferably, externally (running the score on a new population with similar but not identical characteristics from the one on which it was developed).^{26 29} Caution is needed when extrapolating a risk model or score developed in one population or setting to a different one-for example, secondary to primary care, adults to children, or one ethnic group to another.30

Risk scores and other prognostic models should be subject to "impact studies"—that is, studies of the extent to which the score is actually used and leads to improved outcomes. Although most authors emphasise quantitative evaluation of impact such as through cluster randomised controlled trials,³⁰ much might also be learnt from qualitative studies of the process of using the score, either alone or as an adjunct to experimental trials. One such methodology is realist evaluation, which considers the interplay between context, mechanism (how the intervention is perceived and taken up by practitioners), and outcome.³¹ In practice, however, neither quantitative nor qualitative studies of impact are common in the assessment of risk scores.³⁰

We sought to identify, classify, and evaluate risk models and scores for diabetes and inform their selection and implementation in practice. We wanted to determine the key statistical properties of published scores for predicting type 2 diabetes in adults and how they perform in practice. Hence we were particularly interested in highlighting those characteristics of a risk score that would make it fit for purpose in different situations and settings. To that end we reviewed the literature on development, validation, and use of such scores, using both quantitative data on demographics of populations and statistical properties of models and qualitative data on how risk scores were perceived and used by practitioners, policy makers, and others in a range of contexts and systems.

Methods

Theoretical and methodological approach

We followed standard methodology for systematic reviews, summarised in guidance from a previous study and the York Centre for Reviews and Dissemination.^{32 33} The process was later extended by drawing on the principles of realist review, an established form of systematic literature review that uses mainly qualitative methods to produce insights into the interaction between context, mechanism, and outcome, hence explaining instances of both success and failure.³⁴ Our team is leading an international collaborative study, the Realist and Meta-narrative Evidence Synthesis: Evolving Standards (RAMESES) to develop methodological guidance and publication standards for realist review.³⁵

Search strategy

We identified all peer reviewed cohort studies in adults over age 18 that had derived or validated, or both, a statistically weighted risk model for type 2 diabetes in a population not preselected for known risk factors or disease, and which could be applied to another population. Studies were included that had developed a new risk model based on risk factors and that used regression techniques to weight risk factors appropriately, or validated an existing model on a new population, or did both. Exclusion criteria were cross sectional designs, studies that had not finished recruiting, studies on populations preselected for risk factors or disease, studies that did not link multiple risk factors to form a scoring system or weighted model, screening or early detection studies, genetic studies, case series, studies on under 18s, animal studies, and studies that applied a known risk model or score to a population but did not evaluate its statistical potential.

In January 2011 we undertook a scoping search, beginning with sources known to the research team and those recommended by colleagues. We used the 29 papers from this search to develop the definitive protocol, including search terms and inclusion and exclusion criteria. In February 2011 a specialist librarian designed a search strategy (see web extra) with assistance from the research team. Key words were predict, screen, risk, score, [type two] diabetes, model, regression, risk assessment, risk factor, calculator, analysis, sensitivity and specificity, ROC and odds ratio. Both MESH terms and text words were used. Titles and abstracts were searched in Medline, PreMedline, Embase, and relevant databases in the Cochrane Library from inception to February 2011, with no language restrictions.

Search results from the different databases were combined in an endnote file and duplicates removed electronically and manually. In February and March 2011 two researchers independently scanned titles and abstracts and flagged potentially relevant papers for full text analysis.

Two researchers independently read the interim dataset of full text papers and reduced this to a final dataset of studies, resolving disagreements by discussion. Bilingual academic colleagues translated non-English papers and extracted data in collaboration with one of the research team. To identify recently published papers two researchers independently citation tracked the final dataset of studies in Google Scholar. Reference lists of the final dataset and other key references were also scanned.

Quantitative data extraction and analysis

Properties of included studies were tabulated on an Excel spreadsheet. A second researcher independently double checked the extraction of primary data from every study. Discrepancies were resolved by discussion. Where studies trialled multiple models with minimal difference in the number of risk factors, a judgment was made to extract data from the authors' preferred models or (if no preferences were stated in the paper) the ones judged by two researchers to be the most complete in presentation of data or statistical robustness. Data extraction covered characteristics of the population (age, sex, ethnicity, etc), size and duration of study, completeness of follow-up, method of diagnosing diabetes, details of internal or external validation, or both, and the components and metrics used by authors of these studies to express the properties of the score, especially their calibration and discrimination-for example, observed to predicted ratios, sensitivity and specificity, area under the receiver operating characteristic curve. We aimed to use statistical meta-analysis where appropriate and presented heterogeneous data in disaggregated form.

Qualitative data extraction and analysis

For the realist component of the review we extracted data and entered these on a spreadsheet under seven headings (box 1). One researcher extracted these data from our final sample of papers and another checked a one third sample of these. Our research team discussed context-mechanism-outcome interactions hypothesised or implied by authors and reread the full sample of papers with all emerging mechanisms in mind to explore these further.

Impact analysis

We assessed the impact of each risk score in our final sample using three criteria: any description in the paper of use of the score beyond the population for whom it was developed and validated; number of citations of the paper in Google Scholar and number of these that described use of the score in an impact study; and critical appraisal of any impact studies identified on this citation track. In this phase we were guided by the question: what is the evidence that this risk score has been used in an intervention which improved (or sought to improve) outcomes for individuals at high risk of diabetes?

Prioritising papers for reporting

Given the large number of papers, statistical models, and risk scores in our final sample, we decided for clarity to highlight a small number of scores that might be useful to practising clinicians, public health specialists, or lay people. Adapting previous quality criteria for risk scores,²⁶ we favoured those that had external validation by a separate research team on a different population (generalisability), statistically significant calibration, a discrimination greater than 0.70, and 10 or fewer components (usability).

Results

Figure $1 \parallel$ shows the flow of studies through the review. One hundred and fifteen papers were analysed in detail to produce a final sample of 43. Of these 43 papers, 18 described the development of one or more risk models or scores,8 27 36-51 17 described external validation of one or more models or scores on new populations, 9 10 19 52-65 and eight did both.7 66-72 In all, the 43 papers described 145 risk models and scores, of which 94 were selected for extraction of full data (the other 51 were minimally different, were not the authors' preferred model, or lacked detail or statistical robustness). Of the final sample of 94 risk models, 55 were derivations of risk models on a base population and 39 were external validations (of 14 different models) on new populations. Studies were published between 1993 and 2011, but most appeared in 2008-11 (fig 21). Indeed, even given that weaker cross sectional designs had been excluded, the findings suggest that new risk models and scores for diabetes are currently being published at a rate of about one every three weeks.

Table 1U gives full details of the studies in the sample, including the origin of the study, setting, population, methodological approach, duration, and how diabetes was diagnosed. The studies were highly heterogeneous. Models were developed and validated in 17 countries representing six continents (30 in Europe, 25 in North America, 21 in Asia, 8 in Australasia, 8 in the Middle East, 1 in South America, and 1 in Africa).

Comparisons across studies were problematic owing to heterogeneity of data and highly variable methodology, presentation techniques, and missing data. Cohorts ranged in size from 399 to 2.54 million. The same data and participants were often included in several different models in the same paper. Ten research populations were used more than once in different papers.^{9 10 27 37 41 42 44 46-49 51-56 63-66 70 71} In total, risk models

Box 1: Categories for data entry Intended users Authors' assumptions (if any) about who would use the risk score, on which subgroups or populations Proposed action based on the score result Authors' assumptions (if any) on what would be offered to people who score above the designated cut-off for high risk Mechanism Authors' hypothesised (or implied) mechanism by which use of the score might improve outcomes for patients Descriptor Authors' adjectives to describe their risk model or score Relative advantage Authors' stated concerns about their model or score Real world use, including citation tracking Actual data in this paper or papers citing it on use of the score in the real world

were tested on 6.88 million participants, although this figure includes duplicate tests on the same dataset. Participants aged 18 to 98 were studied for periods ranging from 3.15 to 28 years. Completeness of follow-up ranged from 54% to 99% and incidence of diabetes across the time periods studied ranged from 1.3% to 20.9%.

None of the models in the sample was developed on a cohort recruited prospectively for the express purpose of devising it. Rather, all authors used the more pragmatic approach of retrospectively studying a research dataset that had been assembled some years previously for a different purpose. Forty two studies excluded known diabetes in the inception cohort. Diagnosis of diabetes in a cohort at inception and completion of the study was done in different ways, including self report, patient questionnaires, clinician diagnosis, electronic code, codes from the *International Classification of Diseases*, disease or drug registers, diabetes drugs, dietary treatment, fasting plasma glucose levels, oral glucose tolerance test, and measurement of haemoglobin A_{1e} . In some studies the method was not stated. Half the studies used different diagnostic tests at inception and completion of the study.

One third of the papers focused almost exclusively on the statistical properties of the models. Many of the remainder had a clinician (diabetologist or general practitioner) as coauthor and included an (often short and speculative) discussion on how the findings might be applied in clinical practice. Three described their score as a "clinical prediction rule."^{45 51 59}

Quantitative findings

Table 2U gives details of the components of the 94 risk models included in the final sample and their statistical properties—including (where reported) their discrimination, calibration, sensitivity, specificity, positive and negative predictive value, and area under the receiver operating characteristic curve. Many papers offered additional sophisticated statistical analysis, although there was no consistency in the approach used or statistical tests. Heterogeneity of data (especially demographic and ethnic diversity of validation cohorts and different score components) in the primary studies precluded formal meta-analysis.

All 94 models presented a combination of risk factors as significant in the final model, and different models weighted different components differently. The number of components

in a single risk score varied from 3 to 14 (n=84, mean 7.8, SD 2.6). The seven risk scores that were classified as having high potential for use in practice offered broadly similar components and had similar discriminatory properties (area under receiver operating characteristic curve 0.74-0.85, table 4). Overall, the areas under the receiver operating characteristic curve ranged from 0.60 to 0.91. Certain components used in some models (for example, biomarkers) are rarely available in some pathology laboratories and potentially too expensive for routine use. Some models that exhibited good calibration and discrimination on the internal validation cohort performed much less well when tested on an external cohort,^{62 67} suggesting that the initial model may have been over-fitted by inclusion of too many variables that had only minor contributions to the total risk.⁷³ Although this study did not seek out genetic components, those studies that had included genetic markers alongside sociodemographic and clinical data all found that the genetic markers added little or nothing to the overall model.9 10 36 50

Reporting of statistical data in some studies was incomplete-for example, only 40 of the 94 models quantified any form of calibration statistic. Forty three presented sensitivity and specificity, 27 justified the rationale for cut-off points, 22 presented a positive predictive value, 19 presented a negative predictive value, and 26 made some attempt to indicate the percentage of the population that would need clinical follow-up or testing if they scored as "high risk." Some models performed poorly-for example, there was a substantial gap between expected and observed numbers of participants who developed diabetes over the follow-up period. The false positive and false negative rates in many risk scores raised questions about their utility in clinical practice (for example, positive predictive values ranged from 5% to 42%, negative predictive values from 88% to 99%). However, some scores were designed as non-invasive preliminary instruments, with a recommended second phase involving a blood test.7 43 52 53 55 58 65

Risk models and scores tended to "morph" when they were externally validated because research teams dropped components from the original (for example, if data on these were not available), added additional components (for example, to compensate for missing categories), or modified what counted in a particular category (for example, changing how ethnicity was classified); in some cases these modifications were not clarified. A key dimension of implementation is appropriate adaptation to a new context. It was considered that this did not negate the external validation.

Qualitative findings

Table 3 \Downarrow provides the qualitative findings from the risk scores. Of the 43 papers in the full sample, three did not recommend use of the model tested because the authors believed it had no advantage over existing ones.^{50 56 60} Authors of the other 40 papers considered that at least one of their scores should be adopted and used, and to justify this made various claims. The commonest adjective used by authors to describe their score was "simple" (26 of 43); others mentioned "low cost," "easily implemented," "feasible," and "convenient."

Sixteen of the 43 studies that recommended use of a particular risk model or score did not designate an intended user for it. Some authors assigned agency to a risk score—that is, they stated, perhaps inadvertently, that the score itself had the potential to prevent diabetes, change behaviour, or reduce health inequalities. Although most authors did state an intended target group, this was usually given in vague terms, such as "the general population" or "individuals who are likely to develop diabetes." Eleven of the 43 papers gave a clear statement of what intervention might be offered, by whom, to people who scored above the cut-off for high risk; the other papers made no comment on this or used vague terms such as "preventive measures," without specifying by whom these would be delivered.

In all, authors of the papers in the full sample either explicitly identified or appeared to presume 10 mechanisms (box 2) by which, singly or in combination, use of the diabetes risk score might lead to improved patient outcomes (see table 3).

Risk models and scores had been developed in a range of health systems. Differences in components could be explained partly in terms of their intended context of use. For example, the QDScore, intended for use by general practitioners, was developed using a database of electronic records of a nationally representative sample of the UK general practice population comprising 2.5 million people. The QDScore is composed entirely of data items that are routinely recorded on general practice electronic records (including self assigned ethnicity, a deprivation score derived from the patient's postcode, and clinical and laboratory values).⁸ Another score, also intended to be derived from electronic records but in a US health maintenance organisation (covering people of working age who are in work), has similar components to the QDScore except that ethnicity and socioeconomic deprivation are not included. In contrast, the FINDRISC score was developed as a population screening tool intended for use directly by lay people; it consists of questions on sociodemographic factors and personal history along with waist circumference but does not include clinical or laboratory data; high scorers are prompted to seek further advice from a clinician.⁵² Such a score makes sense in many parts of Finland and also in the Netherlands where health and information literacy rates are high, but would be less fit for purpose in a setting where these were low.

Prioritising scores for practising clinicians

Table 4U summarises the properties of seven validated diabetes risk scores which we judged to be the most promising for use in clinical or public health practice. The judgments on which this selection was based were pragmatic; other scores not listed in table 4 (also see tables 1 and 2) will prove more fit for purpose in certain situations and settings. One score that has not yet been externally validated was included in table 4 because it is the only score already being incentivised in a national diabetes prevention policy. $^{\rm 23}$

Studies of impact of risk scores on patient outcomes

None of the 43 papers that validated one or more risk scores described the actual use of that score in an intervention phase. Furthermore, although these papers had been cited by a total of 1883 (range 0-343, median 12) subsequent papers, only nine of those 1883 papers (table $5\Downarrow$) described application and use of the risk score as part of an impact study aimed at changing patient outcomes. These covered seven studies, of which (to date) three have reported definitive results. All three reported positive changes in individual risk factors, but surprisingly none recalculated participants' risk scores after the intervention period to see if they had changed. While one report on the ongoing FIN-D2D study suggests that incident diabetes has been reduced in "real world" (non-trial) participants who were picked up using a diabetes risk score and offered a package of preventive care,⁷ this is a preliminary and indirect finding based on drug reimbursement claims, and no actual data are given in the paper. With that exception, no published impact study on a diabetes risk score has yet shown a reduction in incident diabetes.

Discussion

Numerous diabetes risk scores now exist based on readily available data and provide a good but not perfect estimate of the chance of an adult developing diabetes in the medium term future. A few research teams have undertaken exemplary development and validation of a robust model, reported its statistical properties thoroughly, and followed through with studies of impact in the real world.

Limitations of included studies

We excluded less robust designs (especially cross sectional studies). Nevertheless, included studies were not entirely free from bias and confounding. This is because the "pragmatic" use of a previously assembled database or cohort brings an inherent selection bias (for example, the British Regional Heart Study cohort was selected to meet the inclusion criteria for age and comorbidity defined by its original research team and oriented to research questions around cardiovascular disease; the population for the QDScore is drawn from general practice records and hence excludes those not registered with a general practitioner).

Most papers in our sample had one or more additional limitations. They reported models or scores that required collection of data not routinely available in the relevant health system; omitted key statistical properties such as calibration and positive and negative predictive values that would allow a clinician or public health commissioner to judge the practical value of the score; or omitted to consider who would use the score, on whom, and in what circumstances. We identified a mismatch between the common assumption of authors who develop a risk model (that their "simple" model can now be taken up and used) and the actual uptake and use of such models (which seems to happen very rarely). However, there has recently been an encouraging-if limited-shift in emphasis from the exclusive pursuit of statistical elegance (for example, maximising area under the receiver operating curve) to undertaking applied research on the practicalities and outcomes of using diabetes risk scores in real world prevention programmes.

Box 2: 10 suggested mechanisms by which diabetes risk scores could help improve patient outcomes

Clinical

Direct impact-clinicians will pick up high risk patients during consultations and offer advice that leads to change in patients' behaviour and lifestyle

Indirect impact-routine use of the score increases clinicians' awareness of risk for diabetes and motivation to manage it

Self assessment

Direct impact—people are alerted by assessing their own risk (for example, using an online tool), directly leading to change in lifestyle Indirect impact—people, having assessed their own risk, are prompted to consult a clinician to seek further tests or advice on prevention

Technological

Individual impact—a risk model programmed into the electronic patient record generates a point of care prompt in the clinical encounter *Population impact*—a risk model programmed into the electronic patient record generates aggregated data on risk groups, which will inform a public health intervention

Public health

Planners and commissioners use patterns of risk to direct resources into preventive healthcare for certain subgroups

Administrative

An administrator or healthcare assistant collects data on risk and enters these onto the patients' records, which subsequently triggers the technological, clinical, or public health mechanisms

Research into practice

Use of the risk score leads to improved understanding of risk for diabetes or its management by academics, leading indirectly to changes in clinical practice and hence to benefits for patients

Future research

Use of the risk score identifies focused subpopulations for further research (with the possibility of benefit to patients in later years)

Strengths and limitations of the review

The strengths of this review are our use of mixed methodology, orientation to patient relevant outcomes, extraction and double checking of data by five researchers, and inclusion of a citation track to identify recently published studies and studies of impact. We applied both standard systematic review methods (to undertake a systematic and comprehensive search, translate all non-English texts, and extract and analyse quantitative data) and realist methods (to consider the relation between the components of the risk score, the context in which it was intended to be used, and the mechanism by which it might improve outcomes for patients).

The main limitation of this review is that data techniques and presentation in the primary studies varied so much that it was problematic to determine reasonable numerators and denominators for many of the calculations. This required us to make pragmatic decisions to collate and present data as fairly and robustly as possible while also seeking to make sense of the vast array of available risk scores to the general medical reader. We recognise that the final judgment on which risk scores are, in reality, easy to use will lie with the end user in any particular setting. Secondly, authors of some of the primary studies included in this review were developing a local tool for local use and made few or no claims that their score should be generalised elsewhere. Yet, the pioneers of early well known risk scores^{49 68} have occasionally found their score being applied to other populations (perhaps ethnically and demographically different from the original validation cohort), their selection of risk factors being altered to fit the available categories in other datasets, and their models being recalibrated to provide better goodness of fit. All this revision and recalibration to produce "new" scores makes the systematic review of such scores at best an inexact science.

Why did we not recommend a "best" risk score?

We have deliberately not selected a single, preferred diabetes risk score. There is no universal ideal risk score, as the utility of any score depends not merely on its statistical properties but also on its context of use, which will also determine which types of data are available to be included.^{75 76} Even when a risk model has excellent discrimination (and especially when it does not) the trade-off between sensitivity and specificity plays out differently depending on context. Box 3 provides some questions to ask when selecting a diabetes risk score.

Risk scores as complex interventions

Our finding that diabetes risk scores seem to be used rarely can be considered in the light of the theoretical literature on diffusion of innovation. As well as being a statistical model, a risk score can be thought of as a complex, technology based innovation, the incorporation of which into business as usual (or not) is influenced by multiple contextual factors including the attributes of the risk score in the eyes of potential adopters (relative advantage, simplicity, and ease of use); adopters' concerns (including implications for personal workload and how to manage a positive score); their skills (ability to use and interpret the technology); communication and influence (for example, whether key opinion leaders endorse it); system antecedents (including a healthcare organisation's capacity to embrace new technologies, workflows, and ways of working); and external influences (including policy drivers, incentive structures, and competing priorities).77 78

Challenges associated with risk scores in use

While the developers of most diabetes risk scores are in little doubt about their score's positive attributes, this confidence seems not to be shared by practitioners, who may doubt the accuracy of the score or the efficacy of risk modification strategies, or both. Measuring diabetes risk competes for practitioners' attention with a host of other tasks, some of which

RESEARCH

Box 3: Questions to ask when selecting a diabetes risk score, and examples of intended use

What is the intended use case for the score?

If intended for use:

In clinical consultations, score should be based on data on the medical record

For self assessment by lay people, score should be based on things a layperson would know or be able to measure

In prevention planning, score should be based on public health data

What is the target population?

If intended for use in high ethnic and social diversity, a score that includes these variables may be more discriminatory

What is expected of the user of the score?

If for opportunistic use in clinical encounters, the score must align with the structure and timeframe of such encounters and competencies of the clinician, and (ideally) be linked to an appropriate point of care prompt. Work expected from the intended user of the score may need to be incentivised or remunerated, or both

What is expected of the participants?

If to be completed by laypeople, the score must reflect the functional health literacy of the target population

What are the consequences of false positive and false negative classifications?

In self completion scores, low sensitivity may falsely reassure large numbers of people at risk and deter them from seeking further advice

What is the completeness and accuracy of the data from which the score will be derived?

A score based on automated analysis of electronic patient records may include multiple components but must be composed entirely of data that are routinely and reliably entered on the record in coded form, and readily searchable (thus, such scores are only likely to be useful in areas where data quality in general practice records is high)

What resource implications are there?

If the budget for implementing the score and analysing data is fixed, the cost of use must fall within this budget

Given the above, what would be the ideal statistical and other properties of the score in this context of use? What trade-offs should be made (sensitivity v specificity, brevity v comprehensiveness, one stage v two stage process)?

bring financial and other rewards. At the time of writing, few opinion leaders in diabetes seem to be promoting particular scores or the estimation of diabetes risk generally-perhaps because, cognisant of the limited impacts shown to date (summarised in table 5), they are waiting for further evidence of whether and how use of the risk score improves outcomes. Indeed, the utility of measuring diabetes risk in addition to cardiovascular risk is contested within the diabetes research community.⁷⁹ In the United Kingdom, the imminent inclusion of an application for calculating QDScore on EMIS, the country's most widely used general practice computer system, may encourage its use in the clinical encounter. But unless the assessment of diabetes risk becomes part of the UK Quality and Outcomes Framework, this task may continue to be perceived as low priority by most general practitioners. Given current evidence, perhaps this judgment is correct. Furthermore, the low positive predictive values may spell trouble for commissioners. Identifying someone as "[possibly] high risk" will inevitably entail a significant cost in clinical review, blood tests, and (possibly) intervention and follow-up. Pending the results of ongoing impact studies, this may not be the best use of scarce resources.

Delivering diabetes prevention in people without any disease requires skills that traditionally trained clinicians may not possess.⁸⁰ We know almost nothing about the reach, uptake, practical challenges, acceptability, and cost of preventive interventions in high risk groups in different settings.¹² The relative benefit of detecting and targeting high risk people rather than implementing population-wide diabetes prevention strategies is unknown.¹³ Effective prevention and early detection of diabetes are likely to require strengthening of health systems and development of new partnerships among the clinicians, community based lifestyle programmes, and healthcare funders.⁸¹

Mechanisms by which risk scores might have impact

Although most authors of papers describing diabetes risk scores have hypothesised (or seem to have assumed) a clinical mechanism of action (that the score would be used by the individual's clinician to target individual assessment and advice), the limited data available on impact studies (see table 5) suggest that a particularly promising area for further research is interventions that prompt self assessment-that is, laypeople measuring their own risk of diabetes. The preliminary findings from the impact studies covered in this review also suggest that not everyone at high risk is interested in coming forward for individual preventive input, nor will they necessarily stay the course of such input. It follows that in areas where aggregated data from electronic patient records are available, the diabetes risk scores may be used as a population prediction tool-for example, to produce small area statistics (perhaps as pictorial maps) of diabetes risk across a population, thereby allowing targeted design and implementation of community level public health interventions.⁸² Small area mapping of diabetes risk may be a way of operationalising the recently published guidance on diabetes prevention from the National Institute for Health and Clinical Excellence, which recommends the use of "local and national tools . . . to identify local communities at high risk of developing diabetes to assess their specific needs."83

Towards an impact oriented research agenda for risk scores

We recommend that funding bodies and journal editors help take this agenda forward by viewing the risk score in use as a complex intervention and encouraging more applied research studies in which real people identified as at "high risk" using a particular risk score are offered real interventions; success in risk score development is measured in terms of patient relevant intermediate outcomes (for example, change in risk score) and final outcomes (incident diabetes and related morbidity) rather than in terms of the statistical properties of the tool; a qualitative component (for example, process evaluation, organisational case study, patient's experience of lifestyle modification) explores both facilitators and barriers of using the score in a real world setting; and an economic component evaluates cost and cost effectiveness.

Conclusion

Millions of participants across the world have already participated in epidemiological studies aimed at developing a diabetes risk score. An extensive menu of possible scores are now available to those who seek to use them clinically or to validate them in new populations, none of which is perfect but all of which have strengths. Nevertheless, despite the growing public health importance of type 2 diabetes and the enticing possibility of prevention for those at high risk of developing it, questions remain about how best to undertake risk prediction and what to do with the results. Appropriately, the balance of research effort is now shifting from devising new risk scores to exploring how best to use those we already have.

We thank Helen Elwell, librarian at the British Medical Association Library, for help with the literature search; Samuel Rigby for manually removing duplicates; and Sietse Wieringa, Kaveh Memarzadeh, and Nicholas Swetenham for help with translation of non-English papers. *BMJ* reviewers Wendy Hu and John Furler provided helpful comments on an earlier draft.

Contributors: DN conceptualised the study, managed the project, briefed and supported all researchers, assisted with developing the search strategy and ran the search, scanned all titles and abstracts, extracted quantitative data on half the papers, citation tracked all papers, checked a one third sample of the qualitative data extraction, and cowrote the paper. TG conceptualised the qualitative component of the study, extracted qualitative data on all papers, independently citation tracked all papers, and led on writing the paper. RM independently scanned all titles and abstracts of the electronic search, extracted quantitative data from some papers, assisted with other double checking, and helped revise drafts of the paper. TD helped revise and refine the study aims, independently double checked quantitative data extraction from all papers, and helped revise drafts of the paper. CM advised on systematic review methodology, helped develop the search strategy, extracted quantitative data from some papers, and helped revise drafts of the paper. TG acts as guarantor.

Funding: This study was funded by grants from Tower Hamlets, Newham, and City and Hackney primary care trusts, by a National Institute of Health Research senior investigator award for TG, and by internal funding for staff time from Barts and the London School of Medicine and Dentistry. The funders had no input into the selection or analysis of data or the content of the final manuscript.

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/coi_disclosure.pdf (available on request from the corresponding author) and declare: no support from any organisation for the submitted work; no financial relationships with any organisations that might have an interest in the submitted work in the previous three years; and no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: Not required.

Data sharing: No additional data available.

What is already known on this topic

The many known risk factors for type 2 diabetes can be combined in statistical models to produce risk scores

What this study adds

Dozens of risk models and scores for diabetes have been developed and validated in different settings

Sociodemographic and clinical data were much better predictors of diabetes risk than genetic markers

Research on this topic is beginning to shift from developing new statistical risk models to considering the use and impact of risk scores in the real world

NS=not stated; WHO=World Health Organization; ICD-10=International Classification of Disease, 10th revision; ICD-9=International Classification of Diseases, ninth revision.

| | | | | | | | | | How | How |
|--------|---------|---------------|--------------|--------------|---------------|--------|----------------|-----------|-------------|-----------|
| | | | | | | | Duration: | | diabetes | incident |
| | | | | Study design | Why inception | | mean (SD), | Age: mean | was | diabetes |
| | | | Name of risk | and sampling | cohort was | Sample | range (years), | (SD) or | excluded at | was |
| Study* | Country | Name of study | score | frame | assembled | size | or as reported | range | inception | diagnosed |

Some studies tested multiple models, with minimal difference in number of risk factors; in such cases authors' preferred models were selected or, if no preference stated, we made our own judgment.

*Bracketed information shows how many scores tested by the original authors were included in this systematic review.

Table 2| Key characteristics of 94 diabetes risk models or scores included in systematic review

| Study | Diabetes incidence (%)* | Components of score | Sensitivity/specificity† | AUROC (95% CI) | Positive/negative predictive value (%) | Calibration | % needing further tests |
|------------------------------------|---|---|--|--------------------------|--|---|----------------------------------|
| Aekplakorn 2006 ⁷ | 11.1 | Age, BMI, waist circumference, hypertension, family history of diabetes in first degree relative | 77/60 | 0.74 (0.71 to 0.78) | NS/NS | Hosmer-Lemeshow P=0.8 | NS |
| Aekplakorn 2006 ⁷ | 5.2 | Age, BMI, waist circumference, hypertension, family history of diabetes in first degree relative | 84.4/52.5 | 0.75 (0.71 to 0.80) | NS/NS | NS | NS |
| Alssema 2008 ⁵² | 22.3 per 1000 person years | Age, BMI, waist circumference, use of antihypertensive drugs, parental history of diabetes, family history of diabetes in first degree relative | 84/42 (cut-off ≥7); 52/76 (cut-off ≥10) | 0.71 (0.68 to 0.75) | 19/94 (cut-off ≥7); 26/91 (cut-off ≥10) | NS | 28 |
| Alssema 2008 ⁵² | 10.7 per 1000 person years | Age, BMI, waist circumference, use of antihypertensive drugs, parental history of diabetes, family history of diabetes in first degree relative | 78/64 (cut-off ≥7); 43/85 (cut-off ≥10) | 0.77 (0.73 to 0.80) | 9/98 (cut-off ≥7); 12/97 (cut-off ≥10) | NS | 16 |
| Alssema 2011 ⁵³ | Range 2.3-9.9 across five substudies | Age, BMI, waist circumference, use of antihypertensive drugs, history of gestational diabetes | NS/NS | 0.77 (0.75 to 0.78) | NS/NS | NS | NS |
| Alssema 201153 | Range 2.3-9.9 across five substudies | Age, BMI, waist circumference, use of antihypertensive drugs, history of gestational diabetes, sex, smoking, family history of diabetes | 76/63 | 0.76 (0.75 to 0.78) | 11/NS | Hosmer-Lemeshow P=0.27 | 40 |
| Balkau 2008 ³⁶ | 7.5 | Waist circumference, smoking, hypertension | NS/NS | 0.71 (NS) | NS/NS | Hosmer-Lemeshow P=0.8 | NS |
| Balkau 2008 ³⁶ | 3.2 | Waist circumference, family history of diabetes, hypertension | NS/NS | 0.83 | NS/NS | Hosmer-Lemeshow P=0.9 | NS |
| Bozorgmanesh 2011 ⁵⁴ | 4.6 | Age, family history of diabetes, hypertension, waist circumference, fasting plasma glucose level, height, pulse, triglyceride-high density lipoprotein ratio | Men 71.6/75.3, women 67.1/85.0 | Men 0.79, women 0.829 | NS/NS | Hosmer-Lemeshow P=0.129 | NS |
| Bozorgmanesh 2011 ⁶⁶ | 4.6 | Age, family history of diabetes, systolic blood pressure, waist-hip ratio, waist-height ratio | NS/NS | 0.75 (0.72 to 0.78) | NS/NS | NS | NS |
| Bozorgmanesh 2011 ⁶⁶ | 4.6 | Family history of diabetes, systolic blood pressure, waist-height ratio, triglyceride-high density lipoprotein ratio, fasting plasma glucose level | NS/NS | 0.85 (0.82 to 0.87) | NS/NS | NS | NS |
| Bozorgmanesh 2011 ⁶⁶ | 4.6 | Family history of diabetes, systolic blood pressure, waist-height ratio, triglyceride-high density lipoprotein ratio, fasting plasma glucose level, two hour postprandial plasma glucose level | NS/NS | 0.86 (0.83 to 0.89) | NS/NS | NS | NS |
| Bozorgmanesh 2011 ⁶⁶ | 4.6 | Systolic blood pressure, waist-height ratio, fasting plasma glucose level, triglyceride-high density lipoprotein ratio, family history of diabetes | 75/77 | 0.83 (0.80 to 0.86) | NS/NS | Hosmer-Lemeshow P=0.631 | NS |
| Bozorgmanesh 2011 ⁶⁶ | 4.6 | NS | NS/NS | 0.78 (0.75 to 0.81) | NS/NS | Hosmer-Lemeshow P=0.264 | NS |
| Bozorgmanesh 2010 ⁵⁵ | 4.6 | "San Antonio diabetes prediction model" | NS/NS | 0.83 (0.80 to 0.86) | NS/NS | Hosmer-Lemeshow P<0.001, when recalibrated P=0.131 | NS |
| Cameron 2008 ⁵⁶ | 2.0 | Age, sex, ethnicity, fasting plasma glucose level, systolic blood pressure, high density lipoprotein cholesterol level, BMI, family history of diabetes | 62.4/82.3 | NS | 11.9/98.3 | NS | 19.3 |

| Authors' assumptions | | | | | | | Citation | |
|---------------------------------------|---|---|---|---|--|---|---|--|
| Study | Who will use risk score, on which subgroups or populations | What will be offered to people who score above cut-off for "caseness" | Mechanism by which use of risk score may improve outcome | Authors' adjectives to describe their risk score | Authors' claims for risk score over others | Authors' stated concerns about their risk score | Data in paper on use of risk score in real world | (Google Scholar) for studies of real world use |
| Chuang 2011 ³⁸ | "Clinical professionals and general subjects," for use in "middle aged Chinese adults living in Taiwan" | NS | Clinical | Simple | Menu of scores (some simple, some more complex with better discrimination); large validation cohort | None | None | 0 |
| Collins 2011 ⁵⁷ | Implicitly, epidemiologists and public health clinicians, for use in UK population | NS | Public health | Useful | Validated by an independent team on an independent cohort (unlike most others) | None | NA (not their risk score) | 0 |
| Gao 2009 ³⁹ | "To be used by laypersons" to detect diabetes and raise awareness, "particularly in low- income countries" | NS | Lay people | Simple | Simple, uses absolute risk, based on prospective cohort | Only moderately good predictive power (AUROC 71%) | None | 0 |
| Guerrero-Romero 2010 ⁵⁸ | Intended users not stated. For use on unselected Latin American population | Blood test, monitoring of risk, preventive intervention targeting particular risk factors | Implicitly, clinical | Quick and easy to use, few laboratory investigations, cheap | Statistically better than other scores for use on a Latin American population | Not shown to be cost effective or to improve quality of life, needs external validation | None | 0 |
| Hippisley-Cox 2009 ⁸ | General practice and public health in areas of high socioeconomic and ethnic diversity; use in "clinical settings" and by lay public through a "simple web calculator" | "To identify and proactively intervene" | Clinical | Simple, good discrimination, well calibrated, readily implementable in primary care, cost effective | Includes deprivation and ethnicity, based on data from general practice record, good statistical properties, well validated, "likely to reduce health inequalities" | Missing values (for example, smoking, ethnicity); internal validation on EMIS only; better design would be a prospective study of inception cohort | None, but authors emphasise that it could be used easily | 46 citations, not relevant |
| Joseph 2010 ⁴⁰ | Implicitly, epidemiologists (focus of paper is identification and refinement of risk factors in a population) | "Lifestyle advice advocating physical activity, healthy low fat diet, and weight reduction" | None specifically hypothesised | NS | More comprehensive, AUROC 0.85, longer follow-up, less bias (for example, in how incident diabetes was diagnosed) | None mentioned | None | 0 |
| Kahn 2009⁴¹ | "Insurers or public health agencies to optimise allocation of preventive medicine resources" | "Preventive interventions" | Clinical, public health | Low cost, clinical, simple | Prospectively validated, may illuminate cause of diabetes by demonstrating new associations | Limited to age 45-65 and to white or black ethnic groups | None | 29 citations, not relevant |
| Kanaya 2005 ⁵⁹ | To identify "older persons who should receive intensive lifestyle intervention" | "Lifestyle modification" | Clinical | Simple | Very simple, validated in several samples | Needs validating in a longitudinal study | None | 0 |

| | Authors' assumptions | | _ | | | | | Citation tracking |
|------------------------------|---|---|---|---|--|---|--|---|
| Study | Who will use risk score, on which subgroups or populations | What will be offered to people who score above cut-off for "caseness" | Mechanism by which use of risk score may improve outcome | Authors' adjectives to describe their risk score | Authors' claims for risk score over others | Authors' stated concerns about their risk score | Data in paper on use of risk score in real world | (Google Scholar) for studies of real world use |
| Kolberg 2009 ⁴² | For use on "individuals at highest risk of developing type 2 diabetes" | "for whom the most comprehensive prevention strategies should be considered" | None specifically hypothesised | Objective, quantitative | Biologically plausible ("multi-biomarker"), convenient, fewer logistical challenges to implementation, better discrimination | Developed in overweight middle aged white people, hence transferability may be limited | None | 29 citations, not relevant |
| Lindstrom 2003 ⁶⁸ | Intended users not stated. Implicitly, those who (like the authors) seek to undertake intervention studies of diabetes prevention. For use with "the general public" | "Direct attention to modifiable risk factors." Also, doing one's own risk score might prompt people to modify their lifestyle and prompt them to get their blood glucose level checked | Clinical, lay people | Simple, practical, informative, fast, non-invasive, inexpensive, reliable, safe | Prospective, large cohort. "The public health implications of the Diabetes Risk Score are considerable" | Possible circular argument—identifying people based on same risk factors that would have prompted their clinician to measure random blood glucose level in the first place | Not in this paper, but see citation track | 343 citations, of which eight described impact studies |
| Liu 2011 ⁴³ | Clinicians. "initial instrument for opportunistic screening in general population", "could enhance people's awareness" | Oral glucose tolerance test, education, "opportunity to engage in healthy lifestyles at an early stage" | Clinical | Practical, effective, simple, easily used in clinical practice | Validated on a mainland Chinese population, large cohort, prospective, stable prediction model | Validated in middle aged to older cohort so unproved benefit in younger people. Did not include family history of diabetes, as not on database | None | 0 |
| Mainous 2007 ⁶⁰ | Implicitly, clinicians. Paper describes validation of a previous risk score in a younger cohort | "Early recognition and treatment" | Clinical | NA (they don't recommend it in this group) | NA | Poor discriminatory ability | None | 8 citations, not relevant |
| Mann 2010 ¹⁹ | "Clinicians to stratify their patient populations" | NS | None specifically hypothesised | High discriminative ability | Recalibration and revalidation of Framingham based score in large ethnically diverse population | Inability to isolate Mexicans | None | 3 citations, not relevant |
| McNeely 2003 ⁶¹ | "Clinical practice." To predict diabetes risk in Japanese Americans | NS | None specifically hypothesised | None, all data expressed in numbers | Better in short term than fasting blood glucose test but not in long term (younger people). Not as good as oral glucose tolerance test (older people) | "Further refinements that take into account the differential effects of age are needed" | None | 29 citations, not relevant |
| Mehrabi 201044 | NS | NS | Not specifically hypothesised | Useful, novel | Higher predictability rate than use of single risk factors alone | New and relatively untested, some missing data | None | 0 |
| Meigs 2008 ⁹ | NA—negative study showing that genetic factors add nothing to clinical scores | NA | NA (authors suggest further research on key subgroups) | Less useful than data collected at a routine clinical examination | NA | Did not help to refine the prediction of diabetes risk | NA | 163 citations, but not relevant as paper cited for its negative findings |

| Authors' assumptions | | | _ | | | | | Citation |
|-----------------------------|--|---|---|---|--|--|--|--|
| Study | Who will use risk score, on which subgroups or populations | What will be offered to people who score above cut-off for "caseness" | Mechanism by which use of risk score may improve outcome | Authors' adjectives to describe their risk score | Authors' claims for risk score over others | Authors' stated concerns about their risk score | Data in paper on use of risk score in real world | tracking (Google Scholar) for studies of real world use |
| Nichols 2008 ⁶² | Health maintenance organisations. Based on analysis of electronic record data, to identify members at high risk of developing diabetes | "Interventions" and targeting of healthcare resources | Clinical, public health, technology | "Extremely accurate," simple | Better AUROC | If health maintenance organisation population has different incidence of type 2 diabetes from validation cohort, score will be inaccurate | None | 1 citation, not relevant |
| Rahman 2008 ⁶³ | Primary care and public health clinicians. Use for "defining individuals and populations for testing, treatment and prevention" | Not explicitly stated but authors suggest potential avenues for impact studies | Clinical, public health | Simple, effective | Based on data routinely available on general practice records | Will need to be validated in other prospective cohorts | None | 29 citations, not relevant |
| Rathmann 2010 ⁸⁵ | Intended users not stated. Use "to identify high-risk populations for preventive strategies" | "Preventive strategies" | Public health | Simple | Validated in older population | No external validation yet | None | 1 citation, not relevant |
| Rosella 2010 ⁶⁹ | Public health clinicians and health planners "to estimate diabetes incidence, to stratify the population by risk, and quantify the effect of interventions" | "New intervention strategies" | Public health, clinical | Simple | Uses data available on population registries | Could be further tested on other populations. Family history and poor diet not collected, relies on self reports | None | 1 citation, not relevant |
| Schmidt 2005 ⁴⁶ | Use "in clinical encounters," "by managed care organizations to identify high-risk individuals," and to enrol to clinical trials | "Preventive actions of appropriate intensity" | Clinical, public health, research | Simple, based on readily available clinical information and simple laboratory tests | Good predictor for white and African-American men and women; may apply also to other ethnic groups in United States | High losses to follow-up, oral glucose tolerance test not done at baseline | None | 111 citations, not relevant |
| Schulze 2007 ⁷⁰ | Intended users not stated. "Identifying individuals at high risk of developing T2D [type 2 diabetes] in the general population" | Not explicitly stated | The public | Precise, non-invasive, accurate, useful | Good AUROC (0.84), used absolute values for age rather than broad categories | Self reports may have been biased | None | 114 citations, not relevant |
| Schulze 2009 ⁴⁷ | NS | NS | None specifically hypothesised | Improved discrimination | "A comprehensive basic model," significantly improved by routine blood tests but not chemical or genetic biomarkers | Predictive for onset of diabetes in middle age but not from birth, since diabetes was excluded from inception cohort | None | 17 citations, not relevant |
| Simmons 2007 ⁷¹ | Primary care: "could inform health behaviour information routinely collected in GP consultations or by administrative staff," identify groups for targeted prevention | "Could be incorporated into new patient health checks and may provide a more feasible means of identifying those at risk than OGTT [oral glucose tolerance test], or select those | Clinical, administrative | Simple, feasible | Relies only on simple questions about lifestyle, which would be asked in a routine health check. AUROC (0.76) is as good as many complex risk scores | No better than standard clinical dataset routinely collected in UK general practice (but may be feasible in other health settings) | Feasible to collect | 21 citations, not relevant |

| | Authors' assumptions | | _ | | | | | Citation |
|---------------------------------------|---|---|---|---|---|--|--|--|
| Study | Who will use risk score, on which subgroups or populations | What will be offered to people who score above cut-off for "caseness" | Mechanism by which use of risk score may improve outcome | Authors' adjectives to describe their risk score | Authors' claims for risk score over others | Authors' stated concerns about their risk score | Data in paper on use of risk score in real world | tracking (Google Scholar) for studies of real world use |
| | | suitable for OGTT" | | | | | | |
| Stern 1993 ⁴⁸ | Implicitly, epidemiological researchers | "Identifying high-risk cohorts for prevention trials" | Research, clinical | Predictive, multivariate | Uses commonly measured clinical variables | NS | None | 45 citations, not relevant |
| Stern 2002 ⁸⁶ | "Could be incorporated as it stands into clinical practice and public health practice with the aid of a calculator or personal computer" | Clinical: "patient counselling." Public health: "to identify target populations for preventive interventions" | Clinical, public health, technological, research | Simple | Less expensive and more convenient than oral glucose tolerance testing | Possible missing data | None | 245 citations, not relevant |
| Sun 2009 ⁷² | Use in clinical encounter, by managed care organisations to identify high risk people, and to enrol to clinical trials | Further research | Clinical, technological, research | Simple, effective, accurate | Simple, uses readily available clinical information | Losses to follow-up, oral glucose tolerance test not done at baseline so some cases detected, especially early on, may be prevalent ones | None | 3 citations, not relevant |
| Talmud 2010 ¹⁰ | Intended users not stated (but study used an existing risk score as a "control" for testing a genetic profile) | NS | Not specifically hypothesised | NA (revalidation) | Simple clinical risk scores performed much better than assessment of genetic risk from 40 polymorphisms | NA | None | 21 citations, not relevant |
| Urdea 2009 ⁶⁴ | "Current clinical practice"; for "identifying individuals at highest risk of developing T2DM [type 2 diabetes mellitus]" | "so that clinicians can implement an effective diabetes prevention program" | Clinical | Simple, accurate, convenient | "Better than any other clinical measure", not over-fit, based on multiple biomarkers hence highly plausible | NS | None | 6 citations, not relevant |
| Von Eckardstein 2000 ⁵⁰ | NA (negative study, no better than fasting blood glucose test alone in this cohort) | NA (negative study) | NA | NA (negative study) | NA | Negative study | NA | 56 citations, not relevant |
| Wannamethee 2011 ²⁷ | Intended users not stated | Not stated, unit of analysis is the population | Not specifically hypothesised | NA (less effective than Framingham risk score) | "Useful predictor" (but not as good as Framingham score) | NS | None | 273 citations, not relevant |
| Wannamethee 2005 ⁶⁵ | Intended users not stated | Blood tests | Not specifically hypothesised | Simple, routine | Stepwise | Diabetes diagnosed by self reports | None | 0 |
| Wilson 2007 ⁵¹ | Implicitly, clinicians | Implicitly, lifestyle advice and metformin | Clinical | Simple, effective, easy | Very good AUROC (85%) | NS | None | 143 citations, not relevant |

NS=not stated; NA=not applicable; BMI=body mass index; AUROC=area under receiver operating characteristic curve.

| Score/study name | | | | | External vali | dation |
|--|---|-----------------------------------|--|---|----------------------------------|--|
| country, reference | Risk factors included in score | AUROC | Calibration | Year, country | AUROC | Calibration |
| ARIC (Atherosclerosis Risk in Communities), Germany, Schmidt 2005 ⁴⁶ | Age, ethnicity, waist circumference, height, systolic blood pressure, family history of diabetes, fasting plasma glucose levels, triglyceride levels, high density lipoprotein cholesterol levels | 0.80 | NS | 2010, ¹⁹ USA | 0.84 | Hosmer-Lemeshow P<0.001, after recalibration P>0.10 |
| Ausdrisk, Australia, Chen 2010 ³⁷ | Age, sex, ethnicity, parental history of diabetes, history of high blood glucose, use of antihypertensive drugs, smoking, physical inactivity, waist circumference | 0.78 | Hosmer-Lemeshow P=0.85 | Not externally valid intervention to imp | dated but has b rove outcomes | een studied as part of an ⁸⁷ |
| Cambridge risk score, UK, Rahman 200863 | Age, sex, use of current corticosteroids, use of antihypertensive drugs, family history of diabetes, body mass index, smoking | 0.74 with threshold of 0.38 | NS | 2010, ¹⁰ UK* | 0.72 | Hosmer-Lemeshow P=0.77 |
| FINDRISC, Finland, Lindstrom 2003 ⁶⁸ | Age, body mass index, waist circumference, use of antihypertensive drugs, history of high blood glucose, physical inactivity, daily consumption of vegetables, fruits, and berries | 0.85 | NS | 2010, ⁵³ Holland, Denmark, Sweden, UK, Australia* | 0.76 | Hosmer-Lemeshow P=0.27 |
| Framingham Offspring Study, USA, Wilson 2007 ⁵¹ | Fasting plasma glucose levels, body mass index, high density lipoprotein cholesterol levels, parental history of diabetes, triglyceride levels, blood pressure | 0.85 | NS | 2010, ¹⁹ USA | 0.78 | Hosmer-Lemeshow P<0.001, after recalibration P>0.10 |
| San Antonio risk score, clinical model, USA, Stern 2002 ⁴⁹ | Age, sex, ethnicity, fasting plasma glucose levels, systolic blood pressure, high density lipoprotein cholesterol levels, body mass index, family history of diabetes in first degree relative | 0.84 | Hosmer-Lemeshow P>0.2 | 2010, ¹⁹ USA; 2010, ⁵⁵ Iran*; 2010, ¹⁰ UK*; 2010, ⁶⁶ Iran* | 0.83; 0.83; 0.78; 0.78 | Hosmer-Lemeshow P<0.001, after recalibration P>0.10; Hosmer-Lemeshow P \leq 0.001, after recalibration P=0.131; Hosmer-Lemeshow P=0.42; Hosmer-Lemeshow P=0.264 |
| QDScore, UK, Hippisley-Cox 2009 ⁸ | Age, sex, ethnicity, body mass index, smoking, family history of diabetes, Townsend deprivation score, treated hypertension, cardiovascular disease, current use of corticosteroids | 0.83 men, 0.85 women | Brier score: 0.078 men, 0.058 women | 2011, ⁵⁷ UK | 0.80 men, 0.81 women | Brier score: 0.053 men, 0.041 women |

Table 4| Components of seven diabetes risk models or scores with potential for adaptation for use in routine clinical practice

AUROC=area under receiver operating characteristic curve; NS=not stated.

*Validation used more, less, or substituted risk factors from original risk score or did not state the exact factors it used. See table 2 for further details.

| Table 5 Results of impact citation search (studies using diabetes risk models or scores as part of an intervention to improve outcomes) | | | | | | | | | |
|--|-------------------------|--|--|---|--|---|--|--|--|
| Study (acronym) | Score used | Research question | Setting and sample | Study design, intervention | Main findings or expected reporting date | Comment | | | |
| Absetz 2009 (GOAL study) ⁸⁸ | FINDRISC ⁵⁸ | Can diabetes risk be reduced by lifestyle counselling? | Australia, 352 high risk adults | Real world feasibility study: eight lifestyle counselling sessions | 271/352 completed study. Showed statistically significant reduction in weight, body mass index, and total cholesterol level, maintained at 36 months | Changes only reported on "completers"; those lost to follow-up were not included in analysis. Absolute changes were small and probably not clinically significant—for example, mean 1 kg weight loss. Change in FINDRISC score was not reported | | | |
| Jallinoja 2008 (GOAL study) ⁸⁹ | FINDRISC ⁶⁸ | What is the experience of lifestyle change in people recruited into diabetes prevention studies? | Australia, 30 weight losers and 30 weight gainers from GOAL study | Focus groups with weight losers and weight gainers studied separately | Many found dietary change difficult and stressful; some who did not achieve weight loss felt despondent | Some but not all people encouraged to change lifestyle will achieve it, but most will struggle | | | |
| Colaguiri 2010 (Sydney DPP) ⁸⁷ | AUSD-RISK ³⁷ | Can diabetes risk be reduced by a programme of intensive behaviour change? | Australia, 1550 high risk adults (100 indigenous people) | Real world feasibility study: individual assessment followed by group sessions | Results expected 2013. Main outcomes will be change in weight, physical activity, diet, fasting glucose levels, blood pressure, lipid levels, quality of life, and health service utilisation | Participants will be recruited in primary care, but intervention will be delivered as a public health/community based programme | | | |
| Kulzer 2009 (PREDIAS) ⁹⁰ | FINDRISC ⁶⁸ | Can diabetes risk be reduced by lessons in lifestyle modification? | Germany, 182 high risk adults | Randomised trial. Intervention group received 12 group lessons in lifestyle modification, controls had leaflet | Statistically significant changes in weight, physical activity, diet, and fasting glucose levels at 12 months compared with controls | Weight loss in intervention group was clinically significant (3.8 kg); fasting glucose in the control group increased, whereas that in the intervention group decreased. However, follow-up was short | | | |
| Laatikainen 2007 (GGTDPP) ⁹¹ | FINDRISC ⁶⁸ | Can risk factor reduction be achieved in a high risk non-trial population? | Australia, 237 high risk adults | Real world feasibility study: six sessions of nurse led group education | Statistically significant improvements in weight, fasting and two hour glucose levels, and lipid levels at 12 months | Mean weight loss 2.52 kg. Authors view findings as "convincing evidence that a type 2 diabetes prevention programme using lifestyle intervention is feasible in Australian primary health care with reductions in risk factors approaching those observed in randomised controlled trials" | | | |
| Saaristo 2007 (FIN-D2D) ⁸⁰ and Lindstrom 2010 (FIN-D2D) ⁷⁴ | FINDRISC ⁶⁸ | Can a population approach detect high risk people, modify their risk through educational intervention, and thereby reduce the incidence of new diabetes? | Finland, high risk adults (part of a national diabetes prevention programme that also included population component) | High scorers on FINDRISC had oral glucose tolerance and lipid levels tested; those without diabetes were offered nurse led community based individual or group sessions, or both, based on stages of charge and tailored to individual profile | Preliminary results only. Numbers and detailed findings not given. "Desirable changes" at 12 months in risk factors and glucose tolerance in high risk cohort. Incident diabetes reduced (as measured by drug reimbursement registration data). Full results expected 2012-13 | Authors report that "certain problems and challenges were encountered, especially in relation to the limited resources allotted to preventive health-care." ⁷⁴ A smaller ongoing prevention programme using FINDRISC along with occupational health screening on an occupational cohort in an airline company (FINNAIR diabetes prevention study) is also briefly outlined in Lindstrom paper ⁷⁴ | | | |
| Schwarz 2007 (TUMANI) ⁵⁹ | FINDRISC ⁵⁸ | Can an intensive, multifaceted public health intervention prevent incident diabetes in high risk people? | Germany, high risk adults (part of a national prevention programme) | High scorers on FINDRISC had oral glucose tolerance test before being assigned a "prevention manager" for education, support, and telephone counselling | Results expected 2012-13 | Authors recognise that prevention on a large scale sits oddly within the existing treatment oriented health system. Key features of TUMANI are prevention managers working within the existing infrastructure, a structured quality control programme, and a population component—for example, website and links to mass media | | | |
| Vermunt 2010 (APHRODITE) ⁹² | FINDRISC ⁶⁸ | Can a mailed questionnaire from general practice identify high risk people to participate in a preventive intervention? | Netherlands, 48 general practices | General practitioners mailed questionnaires to their adult patients. High scorers were offered oral glucose tolerance test | 16 032 people were mailed; response rate to questionnaire 54.6%, of which 17.5% were classified as high risk. Of these, 73.1% booked a consultation with their general practitioner. Full results expected 2014 | Findings to date suggest that half of high risk patients were willing to fill out the FINDRISC questionnaire and follow-up with their general practitioner. Response rates to questionnaire varied significantly among practices | | | |
